Abstract

The mammalian cochlea undergoes a highly dynamic process of growth and innervation during development. This process includes spiral ganglion neuron (SGN) branch refinement, a process whereby Type I SGNs undergo a phase of “debranching” before forming unramified synaptic contacts with inner hair cells. Using *Sox2*^{CreERT2} and *R26R*^{tdTomato} as a strategy to genetically label individual SGNs in mice of both sexes, we report on both a time course of SGN branch refinement and a role for P2rx3 in this process. P2rx3 is an ionotropic ATP receptor that was recently implicated in outer hair cell spontaneous activity and Type II SGN synapse development (Ceriani et al., 2019), but its function in Type I SGN development is unknown. Here, we demonstrate that P2rx3 is expressed by Type I SGNs and hair cells during developmental periods that coincide with SGN branching refinement. *P2rx3* null mice show SGNs with more complex branching patterns on their peripheral synaptic terminals and near their cell bodies around the time of birth. Loss of *P2rx3* does not appear to confer general changes in axon outgrowth or hair cell formation, and alterations in branching complexity appear to mostly recover by postnatal day (P)6. However, when we examined the distribution of Type I SGN subtypes using antibodies that bind Calb2, Calb1, and Pou4f1, we found that *P2rx3* null mice showed an increased proportion of SGNs that express Calb2. These data suggest P2rx3 may be necessary for normal Type I SGN differentiation in addition to serving a role in branch refinement.

Key words: auditory; cochlea; hair cell; purinergic; spiral ganglion; synapse formation

Significance Statement

P2rx3 receptors are a class of ionotropic purinergic receptors that are expressed in sensory afferent neurons and have been shown to play essential roles in sensory transduction. However, little is known about how P2rx3 functions in neuronal morphogenesis and synaptic connectivity. Here, we found that P2rx3 is expressed by spiral ganglion neurons (SGNs) and hair cells during cochlear development. Using *P2rx3* null mice combined with genetic sparse labeling, we discovered P2rx3 regulates SGN branch refinement, which is a function of P2rx3 distinguishable from the more conventionally-known role in neural transduction. These results offer new insights into how P2rx3 promotes auditory neuron maturation, which may be useful for endeavors aimed at regenerating lost auditory connections in hearing loss.

Introduction

Hearing function depends on the development and maintenance of spiral ganglion neurons (SGNs) and their

precise patterns of wiring with sensory hair cells in the cochlea. SGNs are bipolar neurons that extend peripheral axons toward hair cells, and central axons into the

brainstem as part of the VIIIth cranial nerve (Nayagam et al., 2011). Early in auditory development, SGN progenitors develop into either Type I or Type II SGNs, which innervate inner hair cells and outer hair cells respectively (Appler and Goodrich, 2011; Bulankina and Moser, 2012). Before establishing fully mature connections, the SGN peripheral axons undergo an array of dynamic developmental events including axon outgrowth, target selection, refinement, spontaneous activity, and pruning (Coate et al., 2019). In auditory transduction, glutamate is released from hair cells onto SGNs (Glowatzki and Fuchs, 2002) at ribbon-type synapses, which are formed, in rodent models, during early postnatal stages (Michanski et al., 2019). Recently, advances in single cell RNA sequencing technology helped reveal that Type I SGNs differentiate into three molecularly distinguishable subtypes (Petitpré et al., 2018; Shrestha et al., 2018; Sun et al., 2018), and that their differentiation is driven by synaptic activity (Shrestha et al., 2018; Sun et al., 2018). The subtype of each SGN likely defines its function and synaptic location on inner hair cells (Liberman, 1982; Wu et al., 2016; Sherrill et al., 2019).

The mechanisms that control neuronal morphogenesis and synapse formation are fundamental questions in developmental neurobiology (Luo, 2002). During development, both presynaptic and postsynaptic terminals sculpt their structures by eliminating excessive branches, which is a process of refinement critical for normal function of the nervous system (Gibson and Ma, 2011; Kalil and Dent, 2014; Riccomagno and Kolodkin, 2015; Schuldiner and Yaron, 2015). In the developing auditory system, each SGN extends a single peripheral axon that initially shows extraneous branches (Koundakjian et al., 2007) that are progressively lost as development progresses. Previously, it was shown that Semaphorin-5B/Plexin-A1 interactions are important for these events: Sema5B is expressed by hair cells while PlexinA1 is expressed by SGNs, and loss of either factor leads to more elaborate SGN branching patterns (Jung et al., 2019). Here, we report that signaling by P2rx3 serves a similar role.

ATP serves as the intracellular energy currency but also can be released into the extracellular space to act as a neurotransmitter. There are two large groups of

membrane-bound purinergic receptors: the ionotropic P2X family, which includes seven family members, and the metabotropic P2Y family, which includes eight family members. P2X receptors are ATP-gated cation channels that allow sodium and calcium ions to flow into the cell (Khakh and North, 2006), whereas P2Y receptors transduce ATP signals via G-protein-mediated intracellular signaling pathways (Burnstock, 2006). Intracellular calcium increases result from purinergic receptor activation leading to a variety of signaling responses (Khakh and North, 2012), with increases in neuronal excitability as the most commonly understood response (Burnstock, 2012). For example, in gustatory excitation, P2rx3 receptors are localized postsynaptically at junctions between sensory cells and taste afferents and they have been demonstrated to be the primary receptor for extracellular ATP (Finger et al., 2005). But, purinergic signaling is also known to be involved in a variety of aspects of nervous system development, including neuron proliferation, migration, maturation, differentiation, and survival (Zimmermann, 2011). Notably, P2X signaling has been shown to regulate the actin cytoskeleton in neurites by signaling through cofilin (Homma et al., 2008), suggesting extracellular ATP can regulate dynamic changes in neuronal architecture. In this study, we leveraged sparse neuron labeling techniques and found a novel role for P2rx3 in regulating Type I SGN branch refinement during cochlear development. We also found that P2rx3 is necessary for the development of the normal profile of Type I SGN subtypes.

Materials and Methods

Mouse lines

All animals in this study were maintained in accordance with the Georgetown University Institutional Animal Care and Use Committee (protocol #1147). Both male and female mice were used for all experiments. *P2rx3* null mice (Cockayne et al., 2000) were a kind gift from Thomas Finger at University of Colorado School of Medicine. *P2rx3* knock-out (KO) mice were bred and maintained onto a C57BL/6 background using breeder mice from Charles River Laboratories. *Sox2^{CreER}* and *R26R^{tdTomato}* reporter mice were originally purchased from The Jackson Laboratory (Stocks No. 017593 and 007914). The *Atoh1^{nGFP}* allele (Lumpkin et al., 2003) was also maintained on this line so the positions of hair cells could be referenced. The primers used for genotyping are as follows: *P2rx3* common: AGT GGA GTT CTT GGC TCA GG, *P2rx3* wild-type (WT) reverse: GCT TTT CAC AAC CAC CGA CT, *P2rx3* mutant reverse: CCT TCT TGA CGA GTT CTT CTG AG. *Rosa26* forward: AAG GGA GCT GCA GTG GAG TA, *Rosa26* reverse: CCG AAA ATC TGT GGG AAG TC, *tdTomato* forward: GGC ATT AAA GCA GCG TAT CC, *tdTomato* reverse: CTG TTC CTG TAC GGC ATG G. *Sox2^{CreER}* WT forward: ACC AGC TCG CAG ACC TAC AT, *Sox2^{CreER}* WT reverse: CGG GGA GGT ACA TGC TGA T, *Sox2^{CreER}* mutant forward: CCA AAA ACT AAT CAC AAC AAT CGC, *Sox2^{CreER}* mutant reverse: GGC AAA CGG ACA GAA GCA T. In nearly all experiments, *P2rx3* heterozygous males and females were crossed to

generate KOs and littermate controls (WT). Both left and right ears were used from one animal; typically, *N* (sample size) equals one cochlea, and *n* equals one SGN peripheral axon. For the synapse and neuronal subtype staining experiments, *P2rx3* WT breeding pairs and KO breeding pairs were set up separately and only one ear from one animal was used to generate more diverse biological replicates. In all cases, breeders were strain matched and experimental progeny were age matched. For timed pregnancies, plug dates were assumed to be embryonic day (E)0.5; the day of birth was considered as postnatal day (P)0.

Immunohistochemistry and antibodies

To prepare tissues for immunostaining, whole heads with the brain removed were fixed in 4% paraformaldehyde (PFA) for 45 min at room temperature (RT) and rinsed extensively in $1 \times$ PBS. For synapse staining, tissues were fixed for 25 min in 4% PFA without prior exposure to PBS. For neuronal subtype staining, cochleae were perfused through the round window with 4% PFA without prior exposure to PBS then bath-fixed for 1 h at RT. Bony capsules were decalcified with 0.5 M EDTA for 24 h. For whole-mount preparations, cochlear capsules, stria vascularis, and Reissner's membranes were removed before staining in glass vials. For cross-sections, inner ears were stepped through 10%, 20%, and 30% sucrose and then embedded and frozen in optimal cutting temperature (OCT; Sakura Finetek) and sectioned at 12 μ m. For most staining experiments, primary antibodies were applied at 4°C overnight and secondary antibodies were applied at RT for 1 h. For synapse staining, primary antibodies were applied overnight at 37°C; secondary antibodies were applied overnight at 4°C. For neuronal subtype staining, sections underwent antigen retrieval before immunostaining, which was adopted from (Sherrill et al., 2019). Slides were suspended over boiling water in a steamer, and sodium citrate buffer (10 mM sodium citrate and 0.05% Tween, pH 6.0) was added to cover the surface of each slide. Slides with buffer were steamed for 30 min then cooled at RT for 5 min. They were then rinsed in PBS a minimum of 10 min. For immunostaining that followed, primary antibodies were added to sections overnight at 37°C. Fluorescent secondary antibodies (1:1000) were added to the samples for 1 h.

The antibodies and concentrations used in this paper were as follows: rabbit-anti-GAP43 (Millipore AB5220, 1:1000, RRID: [AB_2107282](#)), goat-anti-Sox10 (R&D System AF2864, 1:500, RRID: [AB_442208](#)), rabbit-anti-dsRed (Clontech 632496, 1:2000, RRID: [AB_10013483](#)), mouse-anti-Tuj1 (Biolegend, 1:1000, RRID: [AB_2313773](#)), rabbit-anti-MyosinVI (Proteus Biosciences 25–6791, 1:1000, RRID: [AB_10013626](#)), goat-anti-MyosinVI (Coate et al., 2015; 1:1000, RRID: [AB_2783873](#)), goat-anti-Sox2 (R&D Systems AF2018, 1:500, RRID: [AB_355110](#)), chicken-anti-neurofilament heavy chain (NFH or NF200; Aves Labs, 1:1000, RRID: [AB_2313552](#)), rabbit-anti-P2rx3 (Alomone Labs APR-016, 1:1000, RRID: [AB_2313760](#)), goat-anti-ribeye (Santa Cruz Biotechnology SC-5967, 1:500, RRID: [AB_2086771](#)), rabbit-anti-shank1a (Neuromics PA19016, 1:1000, RRID: [AB_1622814](#)),

chicken-anti-Calb1 (Abeomics 34–1020, 1:500, RRID: [AB_2810884](#)), rabbit-anti-Calb2 (Thermo Fisher Scientific PA5-34688, 1:1000, RRID: [AB_2552040](#)), and mouse-anti-Pou4f1 (Millipore Sigma MAB1585, 1:100, RRID: [AB_94166](#)). Actin stereocilia bundles were detected by 405-phalloidin conjugate at 1:1000 (Santa Cruz Biotechnology), cell nuclei were detected by DAPI at 1 μ g/ml (Santa Cruz Biotechnology). Host-specific 488 Alexa Fluor, Cy3, and Cy5 secondary antibodies were used (1:500) accordingly.

Experimental design and statistical analyses

All statistical tests were performed using Prism 8.0 (GraphPad). Results were reported as mean $\pm$ SEM. A two-tailed unpaired *t* test with Welch's correction was used to determine statistical significance unless specifically noted; $p \geq 0.05$, ns; $*p < 0.05$; $**p < 0.01$, $***p < 0.001$, $****p < 0.0001$. Please see figure legends for statistical tests and sample sizes.

To quantify cochlear length, measurement lines (in Fiji) were drawn along the region of the inner pillar cells from the apex to the base; 25% of cochlear length was defined as the apical region, 50% as the middle region, and 75% as the basal region for position-matched comparisons. To quantify radial bundle length using NF200-stained whole-mount samples, line length measurements were taken (eight per region of each sample) along the extending radial bundles and then averaged.

Quantifications of sparsely labeled SGN terminals and cell bodies were performed using the filament function of Imaris (Bitplane). High-magnification images were taken using a Zeiss laser scanning confocal microscope (LSM 880) through a 63 $\times$ objective (Plan-Apochromat 63 $\times$ /1.40 Oil DIC M27) at 1024 by 1024 pixels. Z-stacks stepped by optimal 0.42 μ m were adjusted in individual images to include the entire range of terminal arborization. Only non-overlapping terminals were quantified. For reconstructing axonal terminals, the filament starting point was determined based on the first branching point near the inner hair cells. The entire terminal arborization was traced by drawing terminal points. For each neuron, a skeleton fitting the center of the fluorescence intensity and branching points was determined automatically by the software. The reconstructed filament was then manually centered and smoothed once before finishing the final rendering. For the P0 terminal analyses, the terminal ending position of each axon was scored as modiolar, pillar, or ambiguous. For the single-neuron analyses, *n* (sample size) is equal to one axon. Depending on the number of collateral branches, multiple starting points were drawn whenever a branch originated from the main axon.

Quantification of synaptic structures was performed using the surface and spot functions of Imaris. Background subtraction and thresholding was applied uniformly across all samples. For reconstructing Shank1a patches, the Split Touching Objects function was enabled by a constant seed point's diameter to ensure single hair cell reconstruction. Minute values were either deleted as noise or unified to the adjacent hair cell by a cutoff surface area of 1 μ m. For reconstructing ribeye puncta, the Different Spot Sizes (region growing) function was enabled. Estimated XYZ

diameter was determined empirically and kept consistent. Absolute intensity was used for spot region type and region border was used to determine the final rendering.

Type I SGN subtype immunostaining of WT and *P2rx3* KO samples was quantified (blinded to genotype) using ImageJ. A maximum intensity projection was made from images captured with a 20 $\times$ objective (Plan-Apochromat 20 $\times$ /0.8 M27); triple-immunostaining for Pou4f1, Calb1, Calb2 plus DAPI was visualized in four separate channels. To control for any sample-to-sample variation in background levels, pixel intensities were examined on non-SGNs (see arrowheads in 9I-L; possibly Schwann or otic mesenchyme cells). SGNs with strong staining above this value were deemed positive. Pou4f1-positive cells were determined by obvious nuclear staining above background levels. The DAPI channel was used to confirm overlap of Pou4f1 staining with nuclei. We note here that all SGNs show Pou4f1 background staining in the cytoplasm. Anti-Calb2 and anti-Calb1 immunostaining leads to strong signal in both the nucleus and cytoplasm; pixel values of nearby non-SGNs were also used to determine background in these channels. In terms of the workflow, we first determined which SGNs were positive for Pou4f1. We then toggled between channels to determine whether each was also positive for Calb1 or Calb2. Following this, Calb2 and Calb1 single-positive neurons were counted. Finally, overlap between Calb1 and Calb2-positive cells was counted by toggling between channels. Each SGN was annotated along the way to ensure it was not counted twice. Following quantifications, polygons were drawn around SGN bundles to measure the SGN area. SGN density was calculated by dividing total number of cell bodies by the SGN area.

Results

SGN branching refinement occurs during development

Before innervating inner hair cells during cochlear development, Type I SGNs undergo a process of branch refinement (or “debranching”; Fig. 1A) that is dependent, in part, on Semaphorin-5B (Jung et al., 2019). We first wanted to determine the temporal progression of SGN debranching during development and did so by examining cochleae from mice carrying *Sox2*^{CreERT2} (Arnold et al., 2011) and *R26R*^{tdTom} (Madisen et al., 2010). As shown previously (Brooks et al., 2020), without tamoxifen treatment, low levels of Cre activity in these mice leads to tdTomato expression in various cell types such as SGNs, hair cells, Deiters’ cells, and glial cells. The resulting labeling is reliably sparse enough such that we can visualize individual SGN terminals clearly (Fig. 1B,C, arrow). Cochleae were collected at E15.5, E16.5, P4, P8, P11, and P21 (examples shown in Fig. 1D–F). A total of 30–40 SGN peripheral axons from the base for each stage were analyzed using Imaris. As expected, embryonic SGN peripheral axons show high branch number values (Fig. 1G) and branch depth values (Fig. 1H). “Branch depth” values were assigned based on the branching order: primary branch as 1, secondary as 2, tertiary as 3, etc. Average

branch depth was calculated by the sum of each individual branch depth value divided by branch number; the higher branch depth value a particular neuron has, the more complex the terminal arborization. Interestingly, both branch number (ranging between 9 and 12) and depth values (ranging between 1.9 and 2.4) were quite stable between E15.5 and P4. At P8, SGN fibers showed a more narrowed appearance and significantly reduced branch number (3.6 ± 0.4 , $n=39$) and branch depth values (0.8 ± 0.1 , $n=39$; see Tables 1, 2 for statistical comparisons). By P21, the SGNs showed branch number and depth values that suggest a single contact with inner hair cells (branch number, 1.3 ± 0.2 , $n=27$; branch depth, 0.09 ± 0.06 , $n=27$). Many SGNs with single contacts were visible also between P8 and P11 (Fig. 1F). Together, SGN terminal branches clearly refine over the course of a four-week period. From E15.5 to P4, SGN branching values are stable, although this period involves active SGN motility (Coate et al., 2015). Following this period, from P4 to P8, there is a drastic decrease in branch number and complexity. The early phase correlates with the high levels of *P2rx3* receptor expression in SGNs, suggesting a potential role of this ATP-gated ion channel in regulating SGN peripheral axon branching behavior (Fig. 2).

P2rx3 is expressed by SGNs and hair cells during cochlear innervation

Purinergic signaling has been implicated in numerous biological functions, but little is known about its involvement in the developing cochlea. Previously, *P2rx3* protein was shown to be expressed by mouse SGNs and hair cells in the cochlea around the time of birth (Huang et al., 2006). In addition, online databases show *P2rx3* mRNA expressed by SGNs as early as E12.5, and absent after P6 (Visel et al., 2004; Lu et al., 2011; Li et al., 2020), and in hair cells from E16.5 to P3 (Burns et al., 2015; Cai et al., 2015; Elkon et al., 2015; Scheffer et al., 2015). To examine *P2rx3* distribution in the developing cochlea, we performed anti-*P2rx3* antibody staining on cochlear cross-sections from a series of developmental stages (Fig. 2A). For all stages examined, the samples were counterstained with anti-*Sox2* antibodies to show the position of the developing sensory domain (Kiernan et al., 2005) and anti-NF200 antibodies to show the position of the SGNs. At E12.5 and E14.5, *P2rx3* protein is clearly detectable on SGNs but is not detectable on cells within the sensory domain (Fig. 2B,C). By E15.5, developing inner hair cells show *P2rx3* protein at faintly detectable levels (Fig. 2D,E, oC), while SGNs show *P2rx3* at robust levels (Fig. 2D). At E16.5 and E17.5, *P2rx3* receptors are visible on SGNs and all hair cells (Fig. 2E,F); this pattern lasts only through E18.5 when the *P2rx3* signal disappears from the inner hair cell (Fig. 2G, yellow arrowhead). By P0, *P2rx3* expression on outer hair cells becomes minimal (Fig. 2H) and by P6 at the middle turn of the cochlea, neither SGNs nor hair cells show detectable levels of *P2rx3* (Fig. 2I). The white arrowhead in G-I points to outer hair cells. We note here that, at the very apex of the cochlea at P6, *P2rx3* protein was sometimes faintly visible (data not shown). This

Figure 1. A developmental time course of SGN peripheral axonal refinement. **A**, Cartoon schematic showing the approximate time points of SGN maturation. During the third and the last embryonic week of mouse cochlear development, SGNs extend numerous processes to interact with cells in the sensory epithelium. At the end of this week, Type I and Type II SGNs establish contacts with inner hair cells and outer hair cells, respectively. SGNs refine their terminal arborization as they mature and Type I SGN terminals form single connections with IHCs after the first postnatal week. Hair cells between E15.5 and P4 are shaded blue to indicate the period of Semaphorin-5B expression. IHC, inner hair cell; OHC, outer hair cell. E, embryonic day; P, postnatal day. **B**, **C**, Examples of sparse labeling strategy using *Sox2^{CreERT2}; R26R^{tdTom}* to label a subset of neurons (white) in contrast to all neurons labeled by *Tuj1* (blue). The white arrow points to a Type I SGN terminal. **D–F**, Individual sparsely labeled Type I SGN terminal arborizations at three distinct time points throughout development. Yellow arrowheads point to terminal endings which become refined over time. **G**, Scatter plots of individual axonal terminals quantified to show the number of individual branches within each terminal arborization which are reduced over time (in μm , E15.5, 11.8 ± 0.9 , $n=28$, $N=4$; E16.5, 9.2 ± 1.0 , $n=32$, $N=3$; and P4, 9.8 ± 0.6 , $n=36$, $N=6$; P8, 3.6 ± 0.4 , $n=39$, $N=4$; P11, 3.6 ± 0.5 , $n=45$, $N=5$; P21, 1.3 ± 0.2 , $n=27$, $N=5$; one-way ANOVA followed by Tukey's multiple comparisons test). **H**, Scatter plots of individual axonal terminals quantified to show the complexity of each terminal arborization which are reduced over time (E15.5, 2.4 ± 0.1 ; E16.5, 1.9 ± 0.1 ; and P4, 2.1 ± 0.1 ; P8, 0.8 ± 0.1 ; P11, 0.7 ± 0.1 ; P21, 0.09 ± 0.06 ; same samples and statistical tests as in **G**). See [Tables 1, 2](#) for detailed comparisons and results of statistical tests.

temporal pattern of protein expression aligns precisely with the pattern of *P2rx3* mRNA reported previously (Lu et al., 2011; Li et al., 2020). *P2rx3*^{−/−} tissue showed no *P2rx3* immunostaining in SGNs and very faint background staining in hair cells, indicating the antibody is specific (Fig. 2J). During the course of these studies, we co-labeled fixed cochleae with anti-*P2rx3* antibodies and various neuronal markers to determine whether *P2rx3* is

expressed in olivocochlear efferent neurons (Maison et al., 2016) in addition to SGNs. Overall, *P2rx3* does not appear to be expressed by efferents. As shown in [Figure 2K–M](#), *P2rx3* signal is absent from fibers within the intraganglionic spiral bundle (IGSB), which is mostly comprised of the efferent tracks of axons from both medial olivocochlear (MOC) and lateral olivocochlear (LOC) neurons (Frank and Goodrich, 2018).

Table 1: Detailed comparisons of SGN branch numbers at different stages

Branch number Mean $\pm$ SEM	E15 11.8 $\pm$ 0.9	E16 9.2 $\pm$ 1.0	P4 9.8 $\pm$ 0.6	P8 3.6 $\pm$ 0.4	P11 3.6 $\pm$ 0.5	P21 1.3 $\pm$ 0.2
E15 11.8 $\pm$ 0.9	-	-	-	-	-	-
E16 9.2 $\pm$ 1.0	0.0845 n.s. [-0.19, 5.25]	-	-	-	-	-
P4 9.8 $\pm$ 0.6	0.3011 n.s. [-0.73, 4.57]	0.9827 n.s. [-3.17, 1.94]	-	-	-	-
P8 3.6 $\pm$ 0.4	<0.0001 **** [5.58, 10.79]	<0.0001 **** [3.15, 8.16]	<0.0001 **** [3.84, 8.7]	-	-	-

P21 1.3 $\pm$ 0.2	<0.0001 **** [7.62, 13.29]	<0.0001 **** [5.18, 10.67]	<0.0001 **** [5.86, 11.21]	0.1353 n.s. [-0.36, 4.9]	0.1109 n.s. [-0.28, 4.84]	-

In the conjunction cell where different stages in the column and the row meet, the first row indicates *p* values, the second row indicates the designation of statistical significance, the third row indicates 95% confidence intervals. These data show that branch numbers of developing SGNs decrease over time. n.s., not significant. *****p* < 0.0001.

P2rx3 does not mediate SGN peripheral axon outgrowth or hair cell formation

Based on the expression of P2rx3 on SGNs and hair cells during embryonic development, we hypothesized a potential role in promoting early aspects of cochlear afferent innervation, like SGN outgrowth or refinement. Results from previous studies using cultured SGNs (Greenwood et al., 2007) and neural tube explants (Cheung et al., 2005) suggested P2rx3 may regulate axon extension. To examine this, we performed NFH immunostaining on *P2rx3*^{-/-} cochleae and WT littermate controls at multiple embryonic stages, then measured the lengths of radial bundles, which are fasciculated SGN peripheral axons (Fig. 3). At E15.5, no significant

differences were measured between the two genotypes at either apex or base in terms of peripheral axon length (Fig. 3A–C). Similarly, at E17.5 and P0, no differences were measurable (Fig. 3D–F), suggesting that *P2rx3* loss does not impair SGN peripheral axon growth. In addition, we found that treating cultured embryonic SGNs with α , β , meATP, a known P2rx3 agonist (North, 2002), led to no changes in neurite length (data not shown). These data do not support a hypothesis whereby P2rx3 affects SGN extension. The *P2rx3*^{-/-} cochleae also lacked other general developmental defects: at all stages, cochlear length was comparable between *P2rx3*^{-/-} cochleae and controls (data not shown). We also found that the distribution of fibers positive for GAP-43, an efferent

Table 2: Detailed comparisons of SGN branch depth at different stages

In the conjunction cell where different stages in the column and the row meet, the first row indicates *p* values, the second row indicates the designation of statistical significance, the third row indicates 95% confidence intervals. These data showed that branch depth of developing SGNs decreases over time. n.s., not significant. **p* < 0.05; ***p* < 0.01; *****p* < 0.0001.

Figure 2. Expression of P2rx3 in SGNs and hair cells coincides with SGN branch refinement. **A**, Cartoon schematic showing the developing mouse cochlea extending and coiling from E12.5 to P6. Green indicates SGNs and blue indicates cochlear epithelium. **B**, **C**, Cross-section view of E12.5–E14.5, SGNs (white arrows) are closely attached to the epithelium (white arrowhead) as they delaminate. P2rx3 immunostaining (green) is shown in SGNs; Sox2 (blue) shows the cochlear sensory domain and NFH (red) shows the SGN peripheral axons. **D**, At E15.5, as SGNs extend peripheral axons to the organ of Corti (oC), P2rx3 is present on SGN cell bodies, peripheral axons, and newly differentiated inner hair cells. **E**, **F**, At E16.5 and E17.5, SGNs continue to express P2rx3, and as outer hair cells are differentiated, P2rx3 signals appear in outer hair cells (white arrow in **F**) in addition to the inner hair cells. **G**, **H**, At E18.5 and P0, P2rx3 begins to disappear from the inner hair cells (yellow arrowhead in **G**) while being maintained in all SGNs. The white arrowheads in **G–I** point to outer hair cells. **I**, P2rx3 immunostaining is mostly absent at P6 in SGNs and HCs. **J**, A cross-section from a P0 *P2rx3*^{-/-} cochlea demonstrates complete absence of P2rx3 immunostaining. **K–M**, A whole-mount view of an E16.5 cochlea showing P2rx3 present on SGN cell bodies, radial bundles, and axonal terminals; note that P2rx3 antibodies do not overlap with the Tuj1 staining (magenta) of the olivocochlear efferent fibers, which are prominent in the IGSB (white arrowheads).

Figure 3. *P2rx3* is not required for SGN axonal outgrowth. **A, B**, WT and *P2rx3*^{-/-} cochleae at E15.5 were labeled with NFH (gray) to reveal SGN peripheral axon radial bundles (rb). **C**, Quantification of normalized radial bundle length at E15.5. Each datapoint represents one cochlea. *P2rx3*^{-/-} cochleae show normal axonal outgrowth (in μm , WT apex: 30.7 ± 3.6 , $N=6$; KO apex: 30.8 ± 1.4 , $N=7$; WT base: 63.5 ± 2.9 , $N=6$; KO base: 63.1 ± 4.8 , $N=8$; four WT animals from two litters and four KO animals from two litters; comparison between WT and KO apex, $t_{(7)}=0.022$, $p=0.983$; comparison between WT and KO base: $t_{(11)}=0.071$, $p=0.9444$). **D, E**, Littermate control and *P2rx3*^{-/-} cochleae at E17.5 were labeled with NFH (gray) to show SGN radial bundles. Yellow lines indicate radial bundle length. **F**, Quantification of normalized radial bundle length at E17.5 and *P2rx3*^{-/-} is comparable to WT littermates (in μm , WT apex: 114.9 ± 4.1 , $N=8$; KO apex: 124.7 ± 4.6 , $N=8$; WT base: 154.8 ± 3.5 , $N=8$; KO base: 153.6 ± 3.1 , $N=7$; four WT animals from four litters and four KO animals from four litters; comparison between WT and KO apex, $t_{(14)}=1.59$, $p=0.1337$; comparison between WT and KO base: $t_{(13)}=0.26$, $p=0.7955$). **G, H**, Littermate control and *P2rx3*^{-/-} cochleae at P0 were labeled with NFH (green) to show SGN radial bundles and with Myo6 (magenta) to show HCs. **I**, Quantification of normalized radial bundle length at P0. No axonal elongation defect was detected (in μm , WT apex: 154.6 ± 2.6 , $N=6$; KO apex: 154.4 ± 1.9 , $N=6$; WT base: 170.2 ± 2.6 , $N=6$; KO base: 171 ± 1.4 , $N=6$; three WT animals from three litters and three KO animals from three litters; comparison between WT and KO apex, $t_{(9)}=0.058$, $p=0.9548$; comparison between WT and KO base: $t_{(8)}=0.29$, $p=0.7779$). n.s., not significant.

marker (Simmons et al., 1996), was unchanged (Fig. 4A–H). The distribution of Sox10-positive Schwann and supporting cells also did not appear to be affected by *P2rx3* loss (Fig. 4I,J). The lack of phenotype in efferents or Schwann cells was expected given that neither of these

cell types express *P2rx3*. Given that *P2rx3* is expressed by hair cells during development, we asked whether *P2rx3*^{-/-} cochleae showed changes in hair cell differentiation and/or patterning. As shown in Figure 4K,L, *P2rx3*^{-/-} cochleae at E16.5 show a normal distribution

Figure 4. *P2rx3*^{−/−} cochleae develop normal gross morphology. **A–H**, WT and *P2rx3*^{−/−} littermate cochleae at E16.5 were labeled with GAP-43 (green) to show efferent fibers, and NFH (red), and Tuj1 (blue) to show all neuronal processes. No obvious gross innervation defects were observed. **I, J**, Schwann cells labeled with Sox10 (gray) show normal distribution patterns between WT and *P2rx3*^{−/−} cochleae at E17.5. **K, L**, Myo6 immunostaining (gray) shows no morphologic defects between littermate control and *P2rx3*^{−/−} hair cells at E16.5. **M, N**, Stereocilia bundles labeled with Phalloidin (green) and HCs labeled with Myo6 (magenta) show no morphologic defects between WT and *P2rx3*^{−/−} cochleae at P0.

of Myo6-positive hair cells. *P2rx3*^{−/−} cochleae also show normal hair cell stereocilia bundles at P0 indicated by Phalloidin staining (Fig. 4*M,N*), stereocilia are noted with white arrowheads. Patterns of stereocilia were also unchanged in *P2rx3*^{−/−} cochleae at P6 (data not shown). Overall, the loss of *P2rx3* did not alter the gross morphology of either SGNs or hair cells during the developmental period when *P2rx3* is highly expressed.

P2rx3 is necessary for normal SGNs branching patterns

Given how *P2rx3* expression by SGNs during development coincides with their phase of branch refinement, we next asked whether SGNs from *P2rx3*^{−/−} cochleae show changes in branch morphology. To do this, we bred the *P2rx3*^{−/−} line with mice carrying *Sox2*^{CreERT2} and *R26R*^{tdTomato} and analyzed hundreds of individually-labeled SGNs. Among the tdTomato-labeled SGNs from both *P2rx3*^{−/−} and littermate control mice, 9–10% were clearly Type II SGNs and 90–91% were clearly Type I

SGNs (Fig. 5*A,B*). Since this is the expected distribution (Spoendlin, 1969), we believe the labeling to be stochastic. We also note that, among the labeled SGNs, a small proportion failed to extend to the sensory epithelium at P0. Since we were unable to identify these SGNs as Type I or Type II (Fig. 5*A,B*, “ambiguous”), they were excluded from this analysis. After reconstructing and analyzing hundreds of labeled fibers in both genotypes, we found that loss of *P2rx3* renders Type I SGNs with more complex branching patterns at P0 (Fig. 5*C,D*). Figure 5*C',D'* shows examples of labeled SGNs with volumetric reconstructions; magenta labels indicate branch volumes; green spheres indicate branch tips. Compared with controls, SGNs from *P2rx3*^{−/−} mice showed increased branch numbers at both the cochlear apex and base (Fig. 5*E*), suggesting *P2rx3* normally controls the arborization patterns of the SGN peripheral endings. *P2rx3*^{−/−} SGNs showed decreased average branch length values (Fig. 5*F*), which led us to plot branch number against average branch length for each SGN analyzed. After doing this, we found that

Figure 5. *P2rx3*^{-/-} cochleae at P0 show more complex branching patterns at axonal terminals. **A, B**, Pie charts illustrating the composition of Type I and Type II SGNs among all sparsely labeled SGN from WT and *P2rx3*^{-/-} cochleae at P0. **C, C'**, Representative image of Type I SGN terminal arborization from a WT cochlea at P0. Note there are two axonal terminals shown (yellow arrows). **D, D'**, Representative image of Type I SGN terminal arborization from a *P2rx3*^{-/-} cochlea at P0. Note there are two axonal terminals shown (red arrows). **E**, Quantification of branch number at P0. All of the following quantifications are at P0. Each datapoint represents one SGN peripheral axon (WT apex, $n = 98$, KO apex, $n = 107$, WT base, $n = 50$; $N = 8$ from four WT animals, three litters and $N = 6$ from three KO animals, two litters. WT apex: 18.4 ± 0.7 , KO apex: 34.5 ± 1.6 , WT base: 15.8 ± 0.8 , KO base: 23.4 ± 1.2 ; comparisons between WT and KO apex, $t_{(144)} = 8.97$, $p < 0.0001$; between WT and KO base: $t_{(90)} = 5.37$, $p < 0.0001$). **F**, Quantification of average branch length (in μm , WT apex: 3.5 ± 0.1 , KO apex: 2.8 ± 0.07 , WT base: 3.7 ± 0.1 , KO base: 3.0 ± 0.1 ; comparisons between WT and KO apex, $t_{(168)} = 6.12$, $p < 0.0001$; between WT and KO base: $t_{(135)} = 3.70$, $p = 0.0003$). **G**, Regression plot between average branch length and branch number (WT: $Y = -0.08 \cdot X + 4.9$, KO: $Y = -0.02 \cdot Y + 3.5$). **H**, Quantification of total branch length (in μm , WT apex: 61.7 ± 2.3 , KO apex: 90.3 ± 3.8 , WT base: 52.4 ± 2.0 , KO base: 67.2 ± 2.8 ; comparisons between WT and KO apex, $t_{(172)} = 6.39$, $p < 0.0001$, between WT and KO base, $t_{(101)} = 4.29$,

continued

$p < 0.0001$). **I**, Quantification of average branch depth (WT apex: 3.1 ± 0.1 , KO apex: 4.7 ± 0.1 , WT base: 2.8 ± 0.1 , KO base: 3.9 ± 0.2 ; comparisons between WT and KO apex, $t_{(188)} = 9.17$, $p < 0.0001$, between WT and KO base, $t_{(90)} = 5.61$, $p < 0.0001$). **J**, Quantification of total branch volume (in μm^3 , WT apex: 55.1 ± 1.8 , KO apex: 77.4 ± 2.8 , WT base: 51.9 ± 1.9 , KO base: 62.7 ± 2.3 ; comparisons between WT and KO apex, $t_{(181)} = 6.75$, $p < 0.0001$, between WT and KO base, $t_{(112)} = 3.63$, $p = 0.0004$). **K**, Quantification of average branch diameter (in μm , WT apex: 1.1 ± 0.01 , KO apex: 1.1 ± 0.01 , WT base: 1.1 ± 0.01 , KO base: 1.1 ± 0.01 ; comparisons between WT and KO apex, $t_{(203)} = 1.33$, $p = 0.1837$, between WT and KO base, $t_{(129)} = 1.47$, $p = 0.1454$). n.s., not significant. *** $p < 0.001$; **** $p < 0.0001$.

terminals with large branch numbers typically have shorter individual branches, and that *P2rx3* loss exaggerates this effect (control slope = -0.08 ; *P2rx3* $^{-/-}$ slope = -0.02 ; Fig. 5G). These data suggest there is likely a redistribution of cytoskeletal structures in *P2rx3* $^{-/-}$ SGNs. *P2rx3* $^{-/-}$ SGNs also showed an increase in values for total branch length (the sum of all branch lengths; Fig. 5H), average branch depth (a measurement of branch complexity; Fig. 5I), and total branch volume (the sum of all branch volumes; Fig. 5J). Curiously, though, loss of *P2rx3* $^{-/-}$ did not appear to affect branch diameter (Fig. 5K). Overall, these data suggest *P2rx3* normally maintains the proper size of the SGN terminal arbor at the time when hair cells become innervated.

Although Type I SGNs are all similar in appearance, they are quite heterogeneous in terms of their firing characteristics and synaptic positions on inner hair cells (Liberman, 1978, 1982; Frank et al., 2009; Meyer et al., 2009; Wu et al., 2016). In particular, Type I SGNs with high rates of spontaneous discharge tend to contact the side of the inner hair cell nearest the pillar cell, whereas those with low rates of discharge tend to contact the side of the inner hair cell closest to the modiolus. Despite their elaborate branching patterns, we were easily able to distinguish whether individually-labeled Type I SGNs at P0 were positioned on either the modiolar side (Fig. 6A,B, yellow arrowheads) or pillar cell side of the inner hair cells (Fig. 6A,B, red arrowheads). This analysis was assisted by the use of *Atoh1*^{ngGFP} (Lumpkin et al., 2003), which allowed us to distinguish different sides of the inner hair cell. Interestingly, the majority of SGN peripheral axons and their small branches appeared to be restricted to either the modiolar or the pillar side (and not somewhere in between) by P0. This implies that early guidance events may control the innervation location of subgroups of SGN peripheral axons as a prelude to their final differentiation. This allowed us to ask whether the loss of *P2rx3* had a more significant impact on either one of these populations. Figure 6A',B' shows views from Figure 6A,B rotated 180° along their vertical axes. In this view, the modiolar and pillar terminations are more easily visualized. Overall, the loss of *P2rx3* did not change the proportion of Type I SGNs that contacted either side of the inner hair cell at P0 (Fig. 6C). Type I SGNs that terminated on the modiolar and pillar cell sides of the inner hair cell appeared to all be equally affected by the loss of *P2rx3*: both populations in *P2rx3* $^{-/-}$ cochleae showed increased branch numbers, decreased average length, and increased total branch length (Fig. 6D–F). So, at P0, while *P2rx3* does not appear to control Type I SGN synaptic position, it appears to

regulate branching in a way that is not specific to Type I SGNs that terminate on either side of the inner hair cell.

During our analysis of the branch refinement defects at the SGN terminals in *P2rx3* $^{-/-}$ cochleae, we noticed that the axonal segments proximal to their cell bodies showed many small protrusions at P0 and that these protrusions (which we term “collateral branches”) seemed more numerous than what is normally seen in controls (Fig. 7). In controls, some collateral branches are localized in the main shaft of both peripheral axons and central axons while others originate from the cell bodies (Fig. 7A,A'). *P2rx3* $^{-/-}$ SGNs clearly showed more collateral branches, akin to the increased branch numbers seen at their peripheral terminals (Fig. 7B,B'). When we analyzed these samples, we defined the segment of the SGN axons adjacent to the SGN cell bodies, but oriented toward the hair cells as the “peripheral” segment (Fig. 7A,B, yellow arrowheads), and the segment of SGN axons adjacent to the cell bodies, but oriented toward the brainstem as the “central” segment (Fig. 7A,B, red arrowhead). Compared with controls, *P2rx3* $^{-/-}$ SGNs showed a significant increase of total branch length and branch number for peripheral and central segments adjacent to the cell bodies (Fig. 7C,D). To determine whether the excessive collateral branches adjacent to the cell bodies of the *P2rx3* $^{-/-}$ SGNs persist into later stages, we collected similar samples at P6, when *P2rx3* is no longer expressed; 333 *P2rx3* $^{-/-}$ SGNs from seven cochleae were scored, and only 11 SGNs exhibited a few small excess collateral branches (Fig. 7E,F). Overall, the loss of *P2rx3* $^{-/-}$ leads to excessive collateral branches on the axonal segments around the cell bodies at P0, but these effects do not appear to be permanent.

***P2rx3* mutants do not show persistent SGN branching defects or altered ribbon synapse distribution**

To ask whether the SGN terminal branching defects in the *P2rx3* $^{-/-}$ SGNs (observed at P0) persisted through the normal phase of branching refinement (starting after P4; Fig. 1), we examined individually-labeled Type I SGNs from *P2rx3* $^{-/-}$ SGNs and controls from mice at P6. Like WT SGNs, *P2rx3* $^{-/-}$ SGNs at P6 showed very little branching and had a smooth, unramified appearance (Fig. 8A,B). After we measured their morphologic attributes (as in Fig. 5), we found that the *P2rx3* $^{-/-}$ SGNs showed no differences in average branch number, average branch length, and average branch depth (Fig. 8C–E). These data suggest that the branching phenotype in the *P2rx3* $^{-/-}$ SGNs largely recovers after the first postnatal week. Moreover, after plotting average branch length against

Figure 6. All *P2rx3*^{-/-} SGNs show branching phenotype. **A, A', B, B'**, Representative images of WT and *P2rx3*^{-/-} Type I SGN terminals innervating the modiolar side of the inner hair cells (away from outer hair cells, yellow arrowhead) and pillar cell side of the inner hair cells (close to outer hair cells, red arrowhead) at P0, respectively. The hair cells (and some supporting cells) shown in blue are a result of *Atoh1*^{hGFP}, which was carried on this line. **C**, Pie charts illustrating the compositions of Type I SGNs among all sparsely labeled neurons from WT and *P2rx3*^{-/-} cochleae at P0. **D**, Quantification of branch number at P0 and all the following quantifications are at P0. Each datapoint represents one SGN terminal arborization (WT modiolar: $n=90$, KO modiolar: $n=65$, WT pillar: $n=103$, KO pillar: $n=81$; $N=8$ from four WT animals, three litters and $N=6$ from three KO animals, two litters. WT modiolar: 14.6 ± 0.7 , KO modiolar: 33.9 ± 2.0 , WT pillar: 19.2 ± 0.7 , KO pillar: 29.1 ± 1.8 ; comparisons between WT and KO modiolar, $t_{(82)}=9.25$, $p < 0.0001$, between WT and KO pillar, $t_{(107)}=5.18$, $p < 0.0001$). **E**, Quantification of average branch length (in μm , WT modiolar: 4.0 ± 0.1 , KO modiolar: 2.9 ± 0.1 , WT pillar: 3.3 ± 0.08 , KO pillar: 2.9 ± 0.07 ; comparisons between WT and KO modiolar, $t_{(150)}=6.00$, $p < 0.0001$, between WT and KO pillar, $t_{(182)}=3.99$, $p < 0.0001$). **F**, Quantification of total branch length (in μm , WT modiolar: 53.3 ± 2.4 , KO modiolar: 93.8 ± 5.1 , WT pillar: 60.2 ± 2.0 , KO pillar: 77.3 ± 3.5 ; comparisons between WT and KO modiolar, $t_{(93)}=7.21$, $p < 0.0001$, between WT and KO pillar, $t_{(130)}=4.28$, $p < 0.0001$). **** $p < 0.0001$.

Figure 7. *P2rx3*^{−/−} cochleae have more collateral branches near SGN cell bodies at P0 but not at P6. **A, A', B, B'**, Representative images of *P2rx3*^{+/+} and *P2rx3*^{−/−} SGN cell body regions showing collateral branches on the peripheral axons (yellow arrowheads) and central axons (red arrowheads) at P0, respectively. The fluorescence signal on the cell bodies was saturated to visualize the collaterals. **C**, Quantification of total branch length at P0 (in μm, WT peripheral, *n* = 190, KO peripheral, *n* = 148, WT central, *n* = 192, KO central, *n* = 147; *N* = 8 from four WT animals, three litters and *N* = 6 from three KO animals, two litters. WT peripheral: 7.5 ± 0.5, KO peripheral: 11.3 ± 0.9, WT central: 16.7 ± 0.7, KO central: 20.7 ± 1.2; comparisons between WT and KO peripheral, *t*₍₂₃₃₎ = 3.81, *p* = 0.0002, between WT and KO central, *t*₍₂₃₈₎ = 2.89, *p* = 0.0042). **D**, Quantification of branch number at P0 (WT peripheral: 2.8 ± 0.1, KO peripheral: 3.8 ± 0.3, WT central: 6.0 ± 0.2, KO central: 6.6 ± 0.3; comparisons between WT and KO peripheral, *t*₍₂₃₉₎ = 3.47, *p* = 0.0006, between WT and KO central, *t*₍₃₀₃₎ = 1.99, *p* = 0.0473). **E, F**, Representative images of *P2rx3*^{+/+} and *P2rx3*^{−/−} SGN cell body regions showing smooth peripheral axons and central axons, respectively, at P6. **p* < 0.05; ***p* < 0.01; ****p* < 0.001.

Figure 8. *P2rx3*^{-/-} SGN axonal terminal branching phenotype is largely normal at P6, and *P2rx3*^{-/-} cochleae show normal pre-synaptic Ribeye and postsynaptic Shank1a structures. **A, B**, Representative images of WT and *P2rx3*^{-/-} Type I SGN terminals at P6. **C**, Quantification of branch number at P6 and all of the following quantifications are at P6. Each datapoint represents one SGN terminal arborization (WT apex, $n = 176$, $N = 8$, KO apex, $n = 99$, $N = 7$, WT base, $n = 106$, $N = 8$, KO base, $n = 113$, $N = 7$; four WT animals from two litters and four KO animals from three litters; WT apex: 15.0 ± 0.5 , KO apex: 16.4 ± 0.8 , WT base: 14.0 ± 0.5 , KO base: 13.7 ± 0.7 ; comparisons between WT and KO apex, $t_{(181)} = 1.48$, $p = 0.1408$, between WT and KO base, $t_{(206)} = 0.39$, $p = 0.6991$,

Average Ribeye volume (in μm^3 , WT apex: 0.17 ± 0.008 , KO apex: 0.19 ± 0.017 , WT mid: 0.19 ± 0.01 , KO mid: 0.19 ± 0.018 , WT base: 0.21 ± 0.01 , KO base: 0.21 ± 0.015 ; comparison in apex: $t_{(10)} = 1.07$, in mid: $t_{(11)} = 0.015$, in base: $t_{(12)} = 0.17$). Comparisons between two genotypes at apex, mid, base indicate a normal presynaptic morphology. n.s., not significant. * $p < 0.05$; ** $p < 0.01$; *** $p < 0.001$; **** $p < 0.0001$.

branch number, we also observed no difference regarding the distribution of the data points in both genotypes (Fig. 8F). However, *P2rx3*^{−/−} SGNs showed a significantly increased average branch diameter in the base and overall increased total branch volume (Fig. 8G,H), indicating some persisting effects from the loss of *P2rx3* signaling. We also found some instances where morphologic measurements differed between the apex and the base in *P2rx3*^{−/−} SGNs, whereas no apex-base differences were seen within WT SGNs. For example, for branch number and average branch depth, values in the *P2rx3*^{−/−} SGNs at the base are consistently reduced compared with the apex (Fig. 8C,E), whereas for average branch diameter, *P2rx3*^{−/−} SGNs showed an increase in the base (Fig. 8G); differences like this were not apparent in controls. So, overall, *P2rx3*^{−/−} SGNs at P6 appear to have recovered from most of the branching defects observed at P0 but retain some modest defects. Given that *P2rx3* expression stops shortly after birth (Fig. 2), there are likely compensatory mechanisms that occur toward the end of first postnatal week that also promote SGN branch refinement.

Next, we wanted to investigate whether the branch pruning defects in *P2rx3*^{−/−} SGNs lead to abnormal ribbon synapse formation. Cochlear ribbon synapses undergo a long and dynamic maturation process starting from late embryonic stage through P30 (Yu and Goodrich, 2014; Michanski et al., 2019). To do this, we stained P6 cochleae with antibodies that mark the presynaptic factor Ribeye, and antibodies that mark the postsynaptic factor Shank1a (Huang et al., 2012). In terms of the postsynaptic environment, Shank1a positive scaffold structures appear cup-shaped at the bottom of the inner hair cells at P6 (Fig. 8I,J). Compared with controls, we found no differences in *P2rx3*^{−/−} cochlea regarding Shank1a volume (Fig. 8M), surface area and sphericity (data not shown). These data

suggest that postsynaptic structures in the *P2rx3*^{−/−} cochlea at P6 are normal. In terms of the presynaptic environment, numerous ribbon bodies localize to the bottom of the inner hair cells with a few dispersed throughout the cytoplasm (Yu et al., 2013). Overall, *P2rx3*^{−/−} cochleae showed similar Ribeye number and average Ribeye volume compared with WT cochlea (Fig. 8N,O). Therefore, despite the possibility that excessive branches and terminal endings might cause malformed synaptic connections between SGN peripheral axons and inner hair cells, we report that *P2rx3*^{−/−} cochleae exhibited a normal distribution of presynaptic and postsynaptic ribbon synapse structures. This is consistent with the observed recovery of SGN terminal branches in *P2rx3*^{−/−} cochleae at P6.

P2rx3^{−/−} cochleae show altered proportions of Type I SGN subtype markers

Recent single-cell RNA sequencing analyses have identified three subpopulations of Type I SGNs (Petitpré et al., 2018; Shrestha et al., 2018; Sun et al., 2018). The three populations are distinguishable by various molecular markers and differentiation is dependent on activity as a result of input from inner hair cells (Shrestha et al., 2018; Sun et al., 2018). Considering that ATP signaling is critical for spontaneous activity in the developing cochlea (Tritsch et al., 2010; Wang and Bergles, 2015), and that *P2rx3* appeared to control normal patterns of branching and maturation during development (Figs. 5–7 here), we predicted that loss of *P2rx3* would impair Type I SGN differentiation. To test this, we collected P30 WT and *P2rx3*^{−/−} cochleae and stained cross-sections simultaneously with antibodies that identify Calbindin (Calb1), Calretinin (Calb2), and the transcription factor Pou4f1. These factors were shown previously to delineate the

three subpopulations of Type I SGNs (Petitpré et al., 2018; Shrestha et al., 2018; Sun et al., 2018), but it was also clear that some Type I SGNs expressed more than one of these factors. While the presence of any combination of these factors does not necessarily indicate functional attributes of the SGNs, any changes in their proportions between groups could indicate altered differentiation. Here, we devised a method of staining and scoring samples to enable us to account for SGNs positive for one or multiple markers (Fig. 9A–H; see Materials and Methods; Brooks et al., 2020). This method is illustrated in Figure 9I–L, where colored circles indicate examples of SGNs counted as positive for one or more marker. The green, salmon, and dark blue circles respectively indicate SGNs positive for Calb1 only, Pou4f1 only, or Calb2 only. The light blue circle highlights an SGN double positive for Calb1 and Calb2; the SGN circled in yellow is double positive for Pou4f1 and Calb1. As shown in Figure 9M, N, we found that the proportion of SGNs expressing Calb2 (Calb2 all) was increased in the *P2rx3*^{−/−} cochleae by 11% in the apex and 9.2% in the base. In the apex of *P2rx3*^{−/−} cochleae, there was a corresponding decrease in SGNs positive only for Calb1, and an increase of SGNs positive for both Calb1 and Calb2 (Fig. 9M, N). The base of *P2rx3*^{−/−} cochleae showed a different scenario: the increase in the entire population of Calb2 expressing cells manifested as a result of an increase in cells positive for Calb2 only. To examine the possibility these differences might be because of SGN death, we also compared SGN density between *P2rx3*^{−/−} cochleae and controls and found no differences (Fig. 9O). Thus, loss of *P2rx3* leads to an increase in the number of Calb2-positive cells. Previously, it was shown that, when Type I SGNs differentiate, they tend to express just one of these factors (Petitpré et al., 2018; Shrestha et al., 2018; Sun et al., 2018). Given this and the increase in numbers of Calb2-positive neurons in the *P2rx3*^{−/−} cochleae, these data support a model whereby *P2rx3* may provide a modest contribution to Type I SGN differentiation.

Discussion

SGNs are the primary afferent neurons that connect the peripheral and the central auditory systems (Appler and Goodrich, 2011; Nayagam et al., 2011; Coate and Kelley, 2013). Making precise connections between SGNs and sensory hair cells depends on numerous events, such as the correct targeting of axonal terminals to either inner or outer hair cells (Coate et al., 2015; Druckenbrod and Goodrich, 2015). One critical aspect of cochlear wiring is that each SGN peripheral axon must refine its elaborate terminal arborization to form a one-to-one connection with a single inner hair cell. Understanding these events in the auditory system will help elucidate how complex neural circuits in other parts of the nervous system refine their connectivity patterns (Jan and Jan, 2003). In this report, we have defined the developmental time course of SGN peripheral axon branching refinement and found that *P2rx3* is an important player in this process (Fig. 10). Future studies will determine the extent to which the action of *P2rx3* in this process is dependent on ATP, and

what downstream signaling events in SGNs might be initiated by *P2rx3* (Fig. 10). *P2rx3* receptors are known to be expressed in a variety of afferent sensory neurons and have been shown to play an essential roles in their excitability (Housley et al., 2009). For example, in the urinary system, *P2rx3* was shown to be expressed by pelvic afferent nerves and is necessary for their activity *in vitro* (Vlaskovska et al., 2001) and *in vivo* (Cockayne et al., 2000). *P2rx3* is also expressed by, and necessary for, the activation of nociceptors (Souslova et al., 2000; Tsuda et al., 2000), taste afferents (Finger et al., 2005; Vandenbeuch et al., 2015), gut afferents (Bian et al., 2003), and many others. As shown here, *P2rx3* is expressed by SGNs and hair cells in the cochlea but is eliminated well before the onset of hearing (Fig. 2). So, it likely does not participate in SGN excitation, which is known to be mediated mainly by AMPA signaling (Glowatzki and Fuchs, 2002), and the extent to which *P2rx3* contributes to prehearing spontaneous activity in the cochlea remains to be seen. To our knowledge, a role in neuron branching refinement, as shown here (Figs. 5, 6), represents a novel function for *P2rx3*.

Here, we showed distinct temporal and spatial expression patterns of *P2rx3* receptors in the developing cochlea. Using anti-*P2rx3* antibody staining, we showed that SGNs express *P2rx3* receptors on their cell bodies and neuronal processes from E12.5 to P6. This period of development corresponds to when SGNs migrate, form contacts with inner and outer hair cells, and undergo branching refinement (Fig. 1). *P2rx3* expression by inner and outer hair cells is considerably more transient: inner hair cells express *P2rx3* from E15.5 to E18.5, and outer hair cells express *P2rx3* from E16.5 to P3. Our results align with and extend previous findings of dynamic *P2rx3* receptor expression from E18 to P6 in the mouse cochlea (Huang et al., 2006). In terms of when *P2rx3* is turned off, *P2rx3* mRNA is mostly undetectable in SGNs after P6 (Lu et al., 2011; Li et al., 2020), and this corresponds with the elimination of *P2rx3* protein expression (Fig. 2). The reduction of *P2rx3* is likely a result of *P2rx3* transcriptional downregulation but could also be related to ligand-activated endocytosis from the plasma membrane (Vacca et al., 2009). The expression of *P2rx3* in hair cells appears to follow a similar time course as *Atoh1*, which is expressed by all hair cells transiently and early in their development (Driver et al., 2013). Given that no obvious morphologic abnormality was observed from our immunostaining studies of hair cells, it appears that *P2rx3* is dispensable for their morphogenesis. What remains to be determined is the extent to which the SGN phenotypes we observed in the *P2rx3*^{−/−} cochleae resulted from a lack of *P2rx3* in SGNs, hair cells, or both. Future investigations of cell type-specific loss of *P2rx3* will shed light on this important issue.

Overall, the data here suggest an inhibitory role for *P2rx3* in maintaining the proper size of the SGN terminal arborization. Since *P2X* receptors are known to induce calcium signals (Khakh and North, 2012), we predict that *P2rx3* activation normally leads to calcium transients that modulate the SGN cytoskeleton as it matures (Fig. 10). In these studies, the earliest developmental stage of *P2rx3*^{−/−} cochleae we examined using the sparse labeling approach was P0. Whether *P2rx3*^{−/−} SGNs show excessive branches earlier than P0

Figure 9. *P2rx3*^{-/-} cochleae show altered proportions of Type I SGN subtype markers. **A–H**, Representative images of WT and *P2rx3*^{-/-} cochlear cross-sections at P30 labeled with Calb1, Pou4f1, and Calb2 to show three Type I SGN subtypes, respectively. White arrow indicates a Calb1/Calb2-double positive neuron. **I–L**, Representative images of a P30 cochlear cross-section immunolabeled with Calb1, Pou4f1, Calb2, and DAPI to illustrate quantification of the three Type I SGN subtypes. Circled SGNs are the same for each image. Circles indicate examples of cells counted as Calb1-positive, Pou4f1-positive, Calb2-positive, Calb1/Calb2-double positive, or Pou4f1/Calb1-double positive. Arrowheads indicate stained areas lacking SGNs; cells like these were used to monitor background fluorescence levels. **M**, Comparisons of subtype proportion in each group. Each 95% CI indicates the difference in means between WT and *P2rx3*^{-/-} in each group. *P2rx3*^{+/+} and *P2rx3*^{-/-} cochlear apex (WT Calb2 all: 0.485 ± 0.021 , KO Calb2 all: 0.597 ± 0.025 , $t_{(10)} = 3.46$, 95% CI [0.03984, 0.1854], $p = 0.0063$; WT Calb1 all: 0.795 ± 0.033 , KO Calb1 all: 0.727 ± 0.027 , $t_{(10)} = 1.6$, 95% CI [-0.1638, 0.02706], $p = 0.141$; WT Pou4f1 all: 0.163 ± 0.027 , KO Pou4f1 all: 0.144 ± 0.016 , $t_{(8)} = 0.62$, 95% CI [-0.09136, 0.05251], $p = 0.5512$; WT Calb2 only: 0.116 ± 0.019 , KO Calb2 only: 0.162 ± 0.029 , $t_{(9)} = 1.34$, 95% CI [-0.03249, 0.1255], $p = 0.2147$; WT Calb1 only: 0.356 ± 0.027 , KO Calb1 only: 0.261 ± 0.02 , $t_{(9)} = 2.83$, 95% CI [-0.1694, -0.01909], $p = 0.0194$; WT Pou4f1 only: 0.086 ± 0.015 , KO Pou4f1 only: 0.108 ± 0.016 , $t_{(10)} = 1.02$, 95% CI [-0.02699, 0.07275], $p = 0.3306$; WT Calb2/Calb1: 0.365 ± 0.021 , KO Calb2/Calb1: 0.433 ± 0.013 , $t_{(8)} = 2.72$, 95% CI [0.01045, 0.1239], $p = 0.0257$; WT Calb1/Pou4f1: 0.074 ± 0.024 , KO Calb1/Pou4f1: 0.033 ± 0.006 , $t_{(6)} = 1.64$, 95% CI [-0.1039, 0.02136], $p = 0.1559$; WT Calb2/Pou4f1: 0.074 ± 0.024 , KO Calb2/Pou4f1: 0.033 ± 0.006 , $t_{(6)} = 1.64$, 95% CI [-0.1039, 0.02136], $p = 0.1559$).

remains to be determined. Since *P2rx3* is expressed as early as E12.5 in SGNs (Fig. 2), it could regulate aspects of branch formation in addition to refinement. In addition, some cellular mechanisms of SGN branch refinement remain unclear: does each small branch retract into the main branch, or does each small branch fragment and slough off into the extracellular space? To approach questions like this and gain further insights into how *P2rx3* receptors contribute to SGN terminal morphogenesis, time-lapse imaging studies will need to be conducted. As shown in Figure 9, we also found that cochleae lacking *P2rx3* showed a modest change in how Type I SGN subtype markers were represented. In particular, *P2rx3*−/− cochleae at P30 showed increased numbers of SGNs that were positive for Calb2. Based on previous work showing that Type I SGN subtypes become distinguishable by marker expression increasingly over developmental time (Shrestha et al., 2018; Sun et al., 2018), this phenotype possibly represents reduced Type I SGN differentiation. Extensive profiling of Type I SGN markers and firing characteristics would need to be done to determine whether *P2rx3* loss leads to any functional changes. As noted below, it is also possible that the increased proportion of Calb2-positive cells in *P2rx3*−/− cochleae could have resulted from altered Ca^{2+} fluctuations.

Previously, *P2rx3* was proposed to inhibit SGN axon outgrowth (Greenwood et al., 2007), but our data here suggest this is not the case: *P2rx3*−/− cochleae showed no differences in radial bundle length compared with controls. However, it is possible that redundant mechanisms might compensate for the loss of *P2rx3* in the context of axon outgrowth. Given the branch morphology phenotype in *P2rx3*−/− cochleae, it was surprising that SGNs lacking *P2rx3* did not show changes in synaptic structures (Fig. 8). It is possible that our staining methods were not sensitive enough to detect subtle changes in ribbon synapse compositions or organization in *P2rx3*−/− cochleae, or it is possible that any defects recovered by P6 along with the branching defects (Fig. 8).

What are the mechanisms by which *P2rx3* controls the dynamics of SGN branch refinement? One possibility is that *P2rx3* signaling may interact with Sema5B/PlexinA1 downstream signals, which was shown previously to serve a role in SGN branching refinement (Jung et al., 2019). Another possibility is that SGN microtubules are normally destabilized by *P2rx3*-mediated increases in calcium (Liu and Dwyer, 2014). In this case, loss of *P2rx3* signaling might lead to more stabilized, and thus more

numerous branches. There are also numerous cytosolic and adhesion factors that respond to calcium to modulate filopodial dynamics during growth cone guidance (Gomez et al., 2001; Gomez and Zheng, 2006; Rosenberg and Spitzer, 2011). Since *P2rx3* likely regulates calcium entry into the SGNs, any one of these factors might participate in SGN branch regulation downstream of *P2rx3*. In addition, nerve growth factor (NGF) signaling was shown to regulate *P2rx3*-mediated synaptic activity by decreasing the phosphorylation of threonine residues on *P2rx3*, which altered its assembly on the membrane (D'Arco et al., 2007). Although NGF has not been reported in the cochlea, it is possible that it or other trophic cues might modulate *P2rx3* activity. Future work will need to dissect the molecular mechanisms of how *P2rx3* signaling in SGNs regulates how their branches are refined during hair cell innervation.

Previously, it was shown that *P2rx3* expression is regulated by several mechanisms (Giniatullin et al., 2008). For example, in trigeminal nociceptive neurons, calcitonin gene-related peptide (CGRP) upregulated *P2rx3* transcription and membrane trafficking via protein kinase A (PKA; Fabbretti et al., 2006). Another study showed that brain-derived neurotrophic factor (BDNF), calcium/calmodulin-dependent kinase II (CaMKII), and cAMP-response element-binding protein (CREB) were involved in *P2rx3* transcriptional regulation (Simonetti et al., 2008). Other *P2rx3* regulators could include C-terminal Src inhibitory kinase (Csk; D'Arco et al., 2009), cyclin-

Figure 10. A model for the role of *P2rx3* in SGN branch refinement. Cartoon schematic illustrating a model whereby *P2rx3* receptors in SGNs possibly detect extracellular ATP, and possibly generate calcium signals that regulate SGN branch refinement.

dependent kinase-5 (Cdk5; Nair et al., 2010), and calcium/calmodulin-dependent serine protein kinase (CASK; Gnanasekaran et al., 2013). In future studies, it will be important to determine whether similar or different mechanisms exist in the cochlea.

The data in this report add to an already existing body of knowledge on purinergic signaling in the developing cochlea. Like other parts of the nervous system such as retina, spinal cord, and hippocampus, which display input-independent spontaneous activity for establishing mature neural circuits (Blankenship and Feller, 2010), the developing cochlea also exhibits spontaneous activity before hearing onset (Wang and Bergles, 2015). Purinergic signaling is known to play an essential role in this aspect of cochlear development (Tritsch et al., 2010). Briefly, ATP released from inner supporting cells activates P2ry1 auto-receptors to release calcium from internal stores, which then opens TMEM16A chloride channels (Wang et al., 2015; Babola et al., 2020). Subsequent potassium release depolarizes inner hair cells, which then propagates spontaneous activity into the brain by releasing glutamate onto Type I SGNs (Babola et al., 2018). There is a large body of evidence that disrupted spontaneous activity patterns impairs refinement of sensory maps (Kandler et al., 2009; Kirkby et al., 2013). In the developing auditory brainstem, the loss of efferent cholinergic neurotransmission alters temporal patterns of spontaneous activity and disrupts topographic refinement of synaptic connections and pruning of axon terminals (Clause et al., 2014). In future work, we will determine the extent to which Ca^{2+} transients are altered in *P2rx3*^{−/−} SGNs, which would link *P2rx3* and Ca^{2+} to SGN branch refinement. Additionally, since Calb2 is a Ca^{2+} binding protein (Schwaller, 2009), changes to the rate or spatial distribution of Ca^{2+} buffering in *P2rx3*^{−/−} SGNs might underlie the more widespread distribution of Calb2 or somehow change its program of expression.

Recently, outer hair cells were also shown to exhibit spontaneous calcium transients, which were stimulated by neighboring Deiters' cells. Pharmacological blockade of *P2rx3* receptors inhibited the firing dynamics of outer hair cells, and this altered normal patterns of outer hair cell ribbon synapse distribution and innervation (Ceriani et al., 2019). Extracellular ATP is also known to excite Type II SGNs (Weisz et al., 2009), and recent studies have shown that purinergic signaling occurs in Type II SGNs in response to hair cell damage (Liu et al., 2015). *P2rx3* protein is expressed by all developing SGNs, and it will be important to determine in future studies if *P2rx3* serves a similar role in the branching behavior of Type II SGNs as it does in Type Is. The scarcity of singly labeled Type II SGNs in the *Sox2*^{CreERT2}; *P26R*^{tdTom} cochleae prevented us from comprehensively studying how Type II SGNs were affected by *P2rx3* in this study.

Purinergic signaling has been implicated in a neuromodulatory role beyond cochlea in the auditory system. P2X receptor expressing bushy cells in the cochlear nucleus showed ATP evoked action potentials and calcium signals. Endogenous extracellular ATP not only facilitates spontaneous activity, but also sound-evoked activity largely during developmental stages (Dietz et al., 2012). It seems that neurotransmission mediated by extracellular purines is

a primitive form of neuronal communication in addition to the dominant glutamatergic transmission. Indeed, ATP modulation matures in a high-to-low frequency pattern in the cochlear nucleus, and this is mediated by *P2rx2/3* receptors, which decrease in activity following development (Jovanovic et al., 2017). In this study, we did not examine the function of *P2rx3* in the wiring of the SGN central axons (which do express *P2rx3*; Fig. 2) with neurons in the cochlear nucleus. In future studies, it will be important to determine whether SGN branching and refinement during connectivity in the cochlear nucleus, as in the periphery, is dependent on *P2rx3*.

Whether loss of *P2rx3* leads to hearing impairment remains an open question. Interestingly, one of the closely related family members of *P2rx3*, *P2rx2*, has been implicated in hearing loss associated with DFNA41 (Yan et al., 2013). *P2rx2* point mutants lacked ATP-evoked inward currents and ATP-stimulated membrane permeability. Both humans carrying this mutation and *P2rx2* null mice showed progressive high-frequency hearing loss (Yan et al., 2013). In a separate study, *P2rx2* null mice failed to develop temporary threshold shift (TTS) making them more susceptible to permanent hearing loss because of synaptic damage (Housley et al., 2013). *P2rx2* receptors are known to form heteromeric trimers with *P2rx3* (Jiang et al., 2003), but given that *P2rx2* does not seem to be expressed in embryonic SGNs or HCs, it is not likely that functional *P2rx2*-containing receptors play a role in early SGN development. Given there is no apparent alteration in SGN numbers or hair cell synaptic contacts in mice lacking *P2rx3* (Figs. 8, 9), it is doubtful they would show any measurable auditory brainstem response (ABR) threshold shift. It is also doubtful that the modest change in SGN subtype marker distribution (Fig. 9) would lead to any ABR threshold changes. Nevertheless, it will be important in future studies to examine whether any of the complex aspects of auditory detection in the ascending auditory system are dependent on *P2rx3*.
