## Visual Abstract

The dendrites of cortical pyramidal neurons receive synaptic inputs from different pathways that are organized according to their laminar target. This architectural scheme provides cortical neurons with a spatial mechanism to separate information, which may support neural flexibility required during learning. Here, we investigated layer-specific plasticity of sensory encoding following learning by recording from two different dendritic compartments, tuft and basal dendrites, of layer 2/3 (L2/3) pyramidal neurons in the auditory cortex of mice. Following auditory fear conditioning, auditory-evoked  $\text{Ca}^{2+}$  responses were enhanced in tuft, but not basal, dendrites leading to increased somatic action potential output. This is in direct contrast to the long held (and debated) hypothesis that, despite extensive dendritic arbors, neurons function as a simple one-compartment model. Two computational models of varying complexity based on the experimental data illustrated that this learning-related increase of auditory responses in tuft dendrites can account for the changes in somatic

## Significance Statement

This study directly investigates whether information processing in neurons is compartmentalized within different dendritic regions. Our findings shed light on the learning-related changes that occur in dendritic compartments residing in different layers of the cortex (i.e., tuft and basal dendrites), illustrating that layer 2/3 (L2/3) pyramidal neurons are able to compartmentalize learning signals which leads to enhanced somatic output. The compartmentalization of experience-dependent plasticity supports flexible sensory processing and may increase the computational power of single pyramidal neurons. In addition, it highlights the special role of tuft dendrites, the target of top-down inputs, in modulating sensory encoding following fear learning.

output. Taken together, we illustrate that neurons do not function as a single compartment, and dendritic compartmentalization of learning-related plasticity may act to increase the computational power of pyramidal neurons.

**Key words:** compartmentalization; dendrites; fear learning; two-photon calcium imaging; whole-cell patch clamp *in vivo*

## Introduction

Cortical pyramidal neurons lay at the heart of sensory processing. As the target of synaptic input, cortical dendrites encode sensory stimuli and perception (Xu et al., 2012; Palmer, 2014; Takahashi et al., 2016, 2020; Ranganathan et al., 2018) and ultimately influence neuronal firing (Stuart et al., 1997; Helmchen et al., 1999; Larkum et al., 1999; Golding et al., 2002; Losonczy et al., 2008; Lavzin et al., 2012; Harnett et al., 2013; Smith et al., 2013; Palmer et al., 2014; Manita et al., 2015). Despite their extensive and distinctive morphology, dendrites have historically been treated as a single entity, acting as a single compartment to sum synaptic input (Rall, 1962; Mainen and Sejnowski, 1996; Segev and Rall, 1998; Häusser and Mel, 2003). However, within a single neuron, different information pathways target different regions of the dendritic tree. Basal dendrites, which emanate from the soma of pyramidal neurons, largely receive sensory input and are thought to play an important role in the processing of sensory feedforward (or bottom-up) information (Bannister, 2005; Petreanu et al., 2009). Conversely, distal tuft dendrites, residing in the upper layers of the cortex, largely receive feedback (or top-down) input from higher order areas (Petreanu et al., 2009) and are thought to play an important role in the modulation of sensory encoding (Cauller, 1995; Petreanu et al., 2012; Larkum, 2013; Makino and Komiyama, 2015; Manita et al., 2015; Roth et al., 2016; Marques et al., 2018; Keller et al., 2020). Since they are morphologically separated, the distal tuft and basal dendrites of cortical pyramidal neurons provides individual neurons with a cellular mechanism to simultaneously and

independently process different information pathways (Koch et al., 1982; Häusser and Mel, 2003; Poirazi et al., 2003; Beaulieu-Laroche et al., 2018). By providing multiple independent integrative units, dendritic compartmentalization in cortical neurons may ultimately act to increase the computational power of individual neurons and support the neural flexibility required during learning (Koch et al., 1982; Häusser and Mel, 2003; Poirazi et al., 2003; Beaulieu-Laroche et al., 2018).

In sensory cortices, learning influences local circuits (Makino and Komiyama, 2015; Audette et al., 2019) leading to local plasticity (Bakin and Weinberger, 1990; Edeline et al., 1993; Weinberger, 1993; Weinberger et al., 1993) and altered network activity (Gdalyahu et al., 2012; Kass et al., 2013; Makino and Komiyama, 2015; Lacefield et al., 2019). Since experience-dependent plasticity can occur at the level of a single dendrite (Holthoff et al., 2006; Makino and Malinow, 2011; Cichon and Gan, 2015; Brandalise et al., 2016; Sandler et al., 2016; Bittner et al., 2017), cortical dendrites are ideal candidates for driving the specific and dynamic changes in sensory processing that occur during learning. Here, we tested this by investigating whether auditory fear learning influences the processing of auditory information in the dendrites of cortical pyramidal neurons. By focusing on both the distal tuft and basal dendrites of layer 2/3 (L2/3) pyramidal neurons, which reside in different cortical layers, we assessed whether learning causes different dendritic compartments to undergo similar plasticity during sensory processing, or whether plasticity is compartmentalized in the physically separate dendrites. Using two-photon  $\text{Ca}^{2+}$  imaging in the auditory cortex of anaesthetized mice, we reveal a learning-related increase in auditory-evoked  $\text{Ca}^{2+}$  responses in tuft, but not basal, dendrites. Fear learning also enhanced the somatic action potential output, despite no change in the auditory-evoked subthreshold voltage response. Computational models based on the experimental data further showed that our results are consistent with tuft dendrites playing a primary role in driving the enhanced somatic output following learning. Taken together, the specific learning-related plasticity in tuft, but not basal, dendrites suggests that plasticity can be compartmentalized within cortical pyramidal neurons, leading to increased somatic output.

## Materials and Methods

All experiments were conducted in strict accordance with the Code of Practice for the Care and Use of Animals for Scientific Purposes (National Health and Medical Research Council, Australia) and guidelines given by the veterinary office at the Florey Institute of Neuroscience and Mental Health.

### Auditory fear conditioning

Mice [C57BL/6; postnatal day (P)42–P70, females] were exposed to an auditory fear conditioning protocol. Mice were placed in fear conditioning chambers (MedAssociates) for 2 min of habituation before trains of auditory tones were presented at 1 Hz (pure tones: 5 or 15 kHz;  $5 \times 500$ -ms duration, 500-ms Inter Stimulus Interval (ISI)). The auditory trains were presented either with (CS+) or without (CS–) a 0.6-mA footshock for six times each (5 s each), in a block design (CS+ following the CS– block). The onset of the footshock coincided with the onset of the last tone in the train of tones. After 24 h, CS+ and CS– were presented again in a different context (eight repetitions each, duration 10 s) and freezing behavior were recorded and compared. Freezing scores were automatically measured by the software (MedAssociates) as the percentage of freezing during auditory stimulus presentation, corrected with the baseline values (first 2 min of habituation). Mice that failed to discriminate between the CS– and CS+ (<30% difference in freezing) were excluded from additional experiments and recordings.

### Virus injections

Mice (C57BL/6; P30–P42) were anaesthetized with isoflurane (3% in 0.75 l/min O<sub>2</sub>) and body temperature was maintained at 36–37°C. Eye ointment was applied to prevent dehydration. Meloxicam (1–3 mg/kg, Ilium) was intraperitoneally injected at the beginning of the surgery. The skin was disinfected with ethanol 70% and betadine and a small slit was made in the skin to expose the skull. A small craniotomy (<0.5 mm) was made over the left auditory cortex (2.5 mm posterior to bregma and 4.5 mm lateral from midline) and the dura was left intact. To obtain sparse labeling of L2/3 pyramidal neurons, a mix of the Cre-dependent Ca<sup>2+</sup> indicator, GCaMP6f (AAV1.Syn.Flex.GCaMP6f.WPRE.SV40, UPenn) and diluted Cre (1:6000; AAV1.hSyn.Cre.WPRE.hGH, UPenn) was injected at a dorsoventral distance of 450  $\mu$ m with a microcapillary pipette. Finally, the skin was sutured and the mouse put back into their cage for a minimum of three weeks to allow expression of GCaMP6f, before two photon imaging.

### Auditory stimulation

During two-photon Ca<sup>2+</sup> imaging and whole-cell patch clamp voltage recordings, auditory stimulation (pure tones: 5 or 15 kHz;  $5 \times 500$ -ms duration, 500-ms ISI; 20 trials each) was provided through a speaker (8  $\Omega$ , 5 W; digikey) positioned on the right side of the mouse ~8–10 cm from the contralateral ear. The auditory stimuli were custom made and delivered with an Arduino processing board at ~70 dB.

### Two-photon Ca<sup>2+</sup> imaging and image analysis

Mice previously transfected with GCaMP6f were initially anaesthetized with isoflurane (3% in 0.75 l/min O<sub>2</sub>) before urethane anesthesia (1.6 g/kg, i.p.; Sigma) was administered. After removing the skin and cleaning the skull with

NaOH (3%), a craniotomy was performed (3 mm diameter) over the virus injection site in the auditory cortex (left hemisphere). A circular coverslip (3 mm diameter, size #1) was placed over the craniotomy and sealed with glue. A custom-made metal head-bar (0.5 g) was attached to the skull using dental cement (paladur, Heraeus). For dendritic imaging, GCaMP6f was excited at 940 nm (~30 mW at the back aperture) with a titanium sapphire laser (140-fs pulse width; SpectraPhysics MaiTai Deepsee) and imaged on a Sutter MoM through a 16 $\times$  Nikon objective (0.8 NA). Emitted light was passed through a dichroic filter (565dcxr, Chroma Technology) and short-pass filtered (ET525/70-2p, Chroma Technology) before being detected by a GaAsP photomultiplier tube (Hamamatsu). Images were acquired at a frequency of 30 Hz (512  $\times$  512 pixels) using ScanImage software. Ca<sup>2+</sup> activity was recorded from visually identified tuft and basal dendrites of L2/3 pyramidal neurons within the auditory cortex at a depth of 30–80 and 150–250  $\mu$ m from the pia surface, respectively. To ensure all reported dendrites are from L2/3 pyramidal neurons, we visually followed tuft dendrites to the soma of origin and performed Z-stacks in all experiments. Horizontal and vertical drifts of imaging frames because of animal motion were corrected by registering each frame to a reference image based on whole-frame cross-correlation. The reference image was generated by averaging frames for a given field of view (FOV) in which motion drifts were minimal (>15 pixels). Regions of interest (ROIs) were selected using the SD of all frames in randomly selected trials (five to eight trials, ~2000–4000 frames, spanning the entire imaging session) and manually drawn using the freehand tool in ImageJ. ROIs were selected so that each ROI represented a single dendrite. For display purposes only, images were gamma corrected.

### Ca<sup>2+</sup> analysis

All Ca<sup>2+</sup> signal processing was performed with custom written MATLAB scripts. Fluorescence traces are expressed as relative fluorescence changes,  $\Delta F/F = (F - F_0)/F_0$ . Ca<sup>2+</sup> responses were smoothed using a Savitzky–Golay filter (second order polynomial and seven sample window). Baseline fluorescence ( $F_0$ ) for each ROI was calculated from the average baseline fluorescence intensity during 5 s before the stimulus onset of each trial. For each dendrite, the Ca<sup>2+</sup> traces for all trials were averaged together to generate a trial-averaged Ca<sup>2+</sup> response. Evoked Ca<sup>2+</sup> responses were detected if they were greater than 3 $\times$  the SD of the baseline (5 s before the auditory stimulus onset). Peak amplitudes of the trial-averaged Ca<sup>2+</sup> responses were measured from when the fluorescence trace crossed the 3 $\times$  baseline SD threshold value. To calculate the integral of the Ca<sup>2+</sup> response, trapezoidal numerical integration was performed on the trial-averaged Ca<sup>2+</sup> response normalized to the maximum amplitude of the evoked response. Unless otherwise stated, data are presented as the mean response and error bars represent the SEM. 3D reconstruction and tracing of tuft dendrites was performed using the NeuTube software. Correlation coefficients

were measured as the total number of  $\text{Ca}^{2+}$  transients occurring within sister dendritic branches during a trial divided by the total number of sister branches recorded for a given neuron.

### Whole-cell recordings under anesthesia

Mice (C57BL/6; P42–P63) were initially anaesthetized with isoflurane (3% in 0.75 l/min  $\text{O}_2$ ) before urethane anesthesia (1.6 g/kg, i.p.; Sigma) was administered. Anesthesia was monitored throughout the experiment, and a top-up dose of 10% of the initial urethane dose was administered when necessary. Body temperature was maintained at 36–37°C. Lidocaine (20 mg/ml, Ilium) was injected around the surgical site on the scalp and the head was stabilized in a stereotaxic frame by a head-plate attached to the skull with dental cement (paladur, Heraeus). A craniotomy was performed over the left auditory cortex ( $\sim 1.5 \times 1.5 \text{ mm}^2$ ), centered at  $-2.5 \text{ mm}$  from bregma and 4.5–5 mm lateral from midline. The dura was surgically removed and the brain was constantly bathed with normal rat ringer (135 mM NaCl, 5.4 mM KCl, 1.8 mM  $\text{CaCl}_2$ , 1 mM  $\text{MgCl}_2$ , 5 mM HEPES) throughout the experiment. Whole-cell *in vivo* patch clamp recordings were performed using a patch pipette (resistance 6–9 M $\Omega$ ) filled with an intracellular solution containing 115 mM potassium gluconate, 20 mM KCl, 10 mM sodium phosphocreatine, 10 mM HEPES, 4 mM Mg-ATP, 0.3 mM Na-GTP, adjusted to pH 7.3–7.4 with KOH. The patch pipette was inserted into the brain at an angle of 30°–40° relative to the cortical surface, to a depth of  $\sim 200 \mu\text{m}$  (to target L2/3 neurons). The pipette was then advanced in steps of 1  $\mu\text{m}$  (to a maximum distance of 300  $\mu\text{m}$  in the hypotenuse trajectory) until a neuron was encountered. Whole-cell voltage recordings were performed from the soma using Dagan BVC-700A amplifiers and were filtered at 10 kHz. Once a whole-cell recording was obtained, the voltage response to incremental current steps (50 pA; 800 ms) was recorded to characterize the neuron. In a subset of neurons which had a low rate of action potential firing, positive holding current was applied to the neuron via the patch pipette ( $\sim 50 \text{ pA}$ ) to provide additional depolarization to lower the threshold for action potential generation. Custom-written Igor software was used for the acquisition and of whole-cell recordings. In a subset of experiments, 5-(and-6)-Tetramethylrhodamine biocytin (biocytin-TMR, ThermoFisher) was added to the patch pipette and released extracellularly after the recordings to identify the auditory cortex *post hoc*. Brains were fixed with paraformaldehyde (PFA; 4%), sliced on a vibratome (200  $\mu\text{m}$ ; Leica) and fluorescence imaging was performed to confirm the location of the recordings.

### Data analysis

For whole-cell recordings, the evoked subthreshold response was analyzed as the integral of the evoked voltage envelope (for each tone) using a custom written script in Igor. The firing rate was measured as the number of action

potential detected in a 500-ms window from each tone onset divided by the number of trials.

### Drug application

During *in vivo* whole-cell patch clamp recordings, APV (200  $\mu\text{M}$  diluted 20 $\times$  in ringer; Tocris) was topically applied over the craniotomy and current clamp recordings were performed.

### Statistical analysis

Data were tested for normality and parametric or non-parametric test were used accordingly using the software GraphPad Prism (version 9.0.0). For paired data, Wilcoxon matched-pairs signed-rank test was used for statistical analysis. For unpaired data, Mann–Whitney test was used for statistical analysis. Statistical tests are reported in each figure caption. All data are reported as mean value  $\pm$  SEM.

### Computational model

A multicompartmental computational model of a L2/3 pyramidal neuron was simulated based on previous work (Palmer et al., 2014). Details of the parameters of the model are given in Extended Data Figure 4-1. The model and code to run all simulations will be available on ModelDB (<https://senselab.med.yale.edu/modeldb/>) at the time of publication. Intrinsic membrane mechanisms were taken from the Hay et al. (2011) layer 5b pyramidal model and consisted of 10 active conductances, internal  $\text{Ca}^{2+}$  dynamics, and passive conductances. Values were chosen by starting with the biophysics of the Hay and colleagues model and modifying them to better fit experimental data for L2/3 pyramidal neurons. The main changes were decreases in  $I_h$  and  $\text{Ca}^{2+}$  HVA and LVA channel conductances and increases in the two  $S_k$  channel conductances (see Extended Data Fig. 4-1 for details).

To model the effects of fear learning, excitatory synaptic input was modelled by a voltage dependent NMDA and voltage independent AMPA conductance at each synapse, using a NEURON mechanism created by Alon Polsky on <http://senselab.med.yale.edu/> and published previously (Larkum et al., 2009). The NMDA conductance was voltage dependent and given by  $g_{\text{NMDA}} = g_{\text{MAX}}(\exp(-t/70) - \exp(-t/3))/(1 + 0.3 \exp(-0.08v))$ , and AMPA conductances were modeled with an instantaneous rise time and decay time constant of 0.5 ms (Larkum et al., 2009). Each synapse had a maximum NMDA to maximum AMPA conductance ratio of 1:1. 75 background synapses were randomly distributed across the neuron and were given maximum conductances of 1 nS. Each background synapse was randomly activated between 10 and 100 Hz. To model stimulus-evoked synaptic input, top-down and bottom-up NMDA/AMPA synapses were distributed with uniform distribution across the tuft and basal dendrites. Each of the sensory inputs fired once at a randomly selected time during the stimulus window of 500 ms. To compare increasing tuft versus basal inputs on the model firing, we simulated 200 basal (or tuft) stimulus-evoked synapses with increasing tuft (or basal) stimulus-evoked

synaptic inputs, from 200–300 synapses. A total of 4730 simulations were run, randomly selecting the locations and timing of each synapses for each simulation.

### Reduced model

To simulate auditory inputs onto a L2/3 pyramidal neurons in a model with fewer parameters, we adopted a composite sigmoid model, previously used to model the interaction of tuft and basal compartments of a L5 pyramidal neuron. This model has considerably fewer parameters, all of which are easily interpretable; they describe two tuft sigmoids which control the threshold and maximum of a basal sigmoid which converts basal input into a firing rate. The form this model took was the following:

$$M(t) = a_1 + \frac{a_2}{1 + e^{-\frac{t-a_3}{a_4}}}$$

$$T(t) = b_1 + \frac{b_2}{1 + e^{-\frac{t-b_3}{b_4}}}$$

$$F(b, t) = c_1 + \frac{M(t)}{1 + e^{-(b-T(t))}}$$

The independent variables  $b$  and  $t$  are the basal and tuft inputs, the functions  $M(t)$  and  $T(t)$  are each sigmoids parametrized by the parameters  $a$  and  $b$ , and control the maximum and threshold values of a third sigmoid,  $F(b, t)$  that describes the transformation of basal input into output frequency. The parameter  $c_1$  describes the baseline firing rate. We binned the 500-ms auditory period into 10 50-ms periods. To find the parameters for our simulations that might fit the multicompartmental data, we employed a genetic algorithm, using the absolute difference between the curves in Figure 4c,f as a loss function. For each simulation we assigned all tuft and basal inputs times by sampling from a uniform distribution from 0 to 500 ms, and then binned each synapse into the 10 time periods of the simulation. For every time period, we ran the inputs through the composite sigmoid model to get a Poisson probability, and then sampled from that distribution to get a number of spikes in that time bin. Doing that for every bin gave us a total spike count, which we then converted into an output frequency, to get the plot in Figure 4f. The code for the reduced model and code for fitting using the genetic algorithm are available online at <https://github.com/adamimos/FearfulDendrites>.

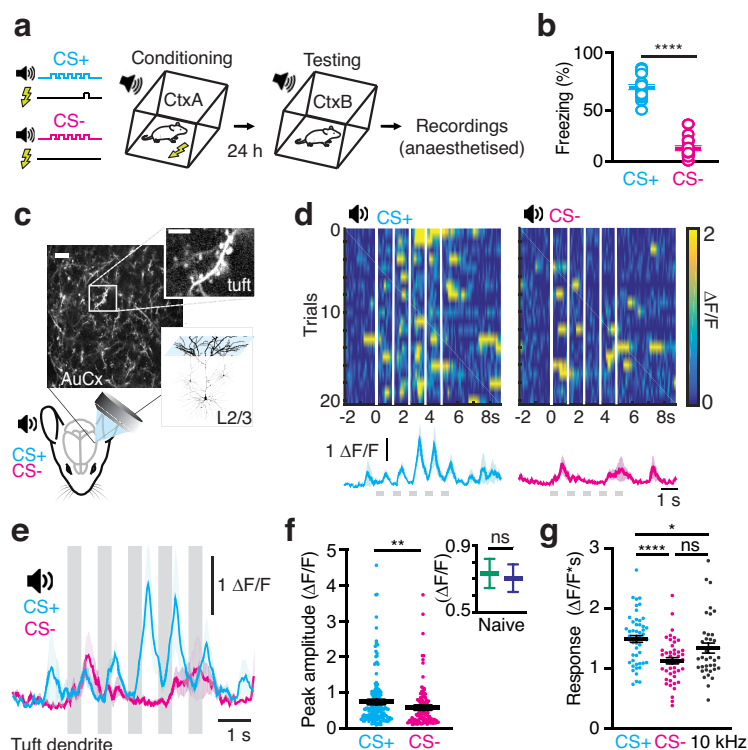

## Results

### Auditory-evoked responses to CS+ are enhanced in tuft dendrites

To assess the influence of learning on dendritic encoding of sensory information, mice were exposed to an auditory fear conditioning protocol that consisted of trains of pure tones ( $5 \times 500$  ms, 5 or 15 kHz) presented with (CS+) or without (CS–) a mild footshock (Yang et al., 2016; Fig. 1a). The auditory stimuli (5 or 15 kHz) were counterbalanced and randomly allocated as either CS+ or CS–. Behavioral freezing responses to the auditory stimuli were

tested the day following conditioning. Conditioned mice discriminated between the two stimuli, with CS+ reliably evoking more freezing compared with CS– ( $68.5 \pm 2.3\%$  vs  $12.3 \pm 2.1\%$ ;  $n = 20$  mice;  $p = 0.0001$ ; Fig. 1b). To determine how the processing of sensory information in cortical dendrites was influenced by fear learning, we performed two-photon calcium imaging in the dendrites of L2/3 pyramidal neurons within the auditory cortex of urethane anesthetized mice sparsely transfected with the genetic  $\text{Ca}^{2+}$  indicator GCaMP6f. Since learning involves feedback information within the upper layers of sensory cortices (Makino and Komiyama, 2015; Doron et al., 2020), we first investigated whether sensory information at the dendritic site of feedback input in pyramidal neurons, tuft dendrites, is altered by auditory fear conditioning. Following the fear conditioning protocol, auditory-evoked  $\text{Ca}^{2+}$  activity was recorded in the tuft dendrites of L2/3 pyramidal neurons ( $<80 \mu\text{m}$  below pia; Fig. 1c,d). Overall, a similar number of tuft dendrites responded to the auditory stimuli presented during fear conditioning (CS+: 20% and CS–: 18%). However, in these dendrites, the peak of the average  $\text{Ca}^{2+}$  response evoked during CS+ was significantly larger than CS– ( $0.74 \pm 0.05$  vs  $0.58 \pm 0.05 \Delta\text{F}/\text{F}$ ;  $n = 52/46$  dendrites, 9 mice;  $p = 0.005$ ; Fig. 1e,f). In contrast, there was no overall difference in the auditory-evoked responses in naive mice (5 and 15 kHz;  $p = 0.52$ ; Fig. 1f; Extended Data Fig. 1–1), suggesting the increased  $\text{Ca}^{2+}$  response to CS+ in tuft dendrites is due to learning-related plasticity of the auditory-evoked response. To further probe whether this increase in dendritic activity was indeed learning dependent and not simply because of stimuli exposure, we compared the average  $\text{Ca}^{2+}$  responses to both CS+ and CS– with a reference stimulus composed of a train of tones not previously presented to the mice ( $5 \times 500$  ms, 10 kHz; Extended Data Fig. 1–2). Here, the overall auditory-evoked  $\text{Ca}^{2+}$  response was significantly larger during CS+ ( $1.48 \pm 0.05 \Delta\text{F}/\text{F}^*$ ;  $n = 52$  dendrites, Fig. 1g) compared with either the CS– ( $1.12 \pm 0.05 \Delta\text{F}/\text{F}^*$ ;  $n = 46$  dendrites;  $p < 0.001$ ; Fig. 1g) or the reference stimulus ( $1.33 \pm 0.08 \Delta\text{F}/\text{F}^*$ ;  $n = 37$  dendrites,  $p = 0.02$ ; Fig. 1g). Importantly, there was no difference in the auditory-evoked  $\text{Ca}^{2+}$  response to CS– and the reference stimulus ( $p = 0.11$ ; Fig. 1g), illustrating that the increase in dendritic activity in response to CS+ was learning dependent and not because of stimuli exposure.

Is this learning-related plasticity encoded locally, on a single dendritic branch, or on multiple tuft dendrites within a single neuron? To address this, we reconstructed L2/3 pyramidal neurons *post hoc* and retrospectively assessed the auditory-evoked  $\text{Ca}^{2+}$  responses to conditioned stimuli in tuft dendrites from the same neurons (Extended Data Fig. 1–3; see Materials and Methods). Identifying branches from the same neuron illustrated that tuft dendrites typically had similar patterns of activity, however, auditory-evoked  $\text{Ca}^{2+}$  events were occasionally localized to a single branch. Following fear learning, the correlation of  $\text{Ca}^{2+}$  transients across tuft dendrites of the same neuron were similar during CS+ and CS– (Extended Data Fig. 1–3), suggesting that fear conditioning did not alter the

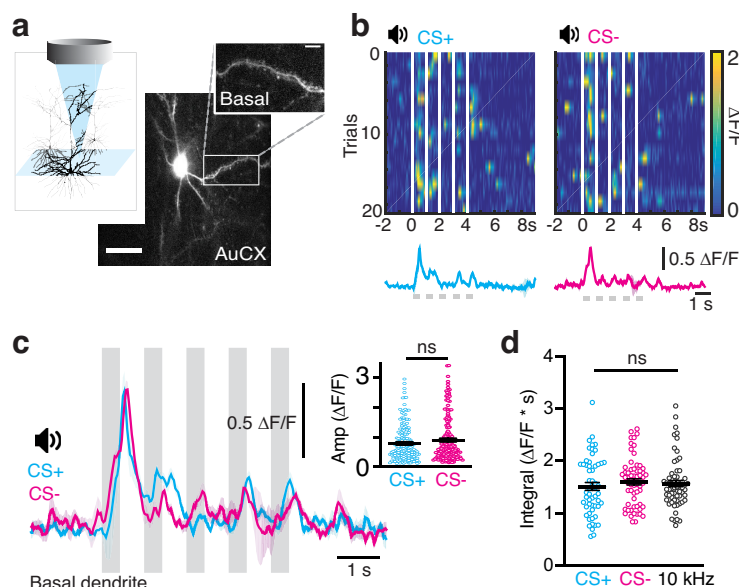

**Figure 1.** Auditory-evoked  $\text{Ca}^{2+}$  responses to CS+ are enhanced in tuft dendrites. **a**, Schematic of the experimental design and of the auditory fear conditioning protocol. **b**, Freezing scores to CS+ and CS– 24 h after conditioning ( $n=20$  mice; paired  $t$  test). **c**, Schematic of the experimental design. Gray bars show the tones in the auditory stimuli. **f**, Peak amplitude of the trial-averaged  $\text{Ca}^{2+}$  responses to CS+ ( $0.74 \pm 0.05 \Delta\text{F}/\text{F}$ ) and CS– ( $0.58 \pm 0.05 \Delta\text{F}/\text{F}$ ). Mann–Whitney test. Inset, Peak amplitude of the trial-averaged  $\text{Ca}^{2+}$  responses in naive mice were not different (see also Extended Data Fig. 1–1). **g**, Integral of the trial-averaged  $\text{Ca}^{2+}$  responses to CS+ ( $1.48 \pm 0.05 \Delta\text{F}/\text{F}\cdot\text{s}$ ), CS– ( $1.12 \pm 0.05 \Delta\text{F}/\text{F}\cdot\text{s}$ ), and a reference stimulus (10 kHz;  $1.33 \pm 0.08 \Delta\text{F}/\text{F}\cdot\text{s}$ ; Extended Data Fig. 1–2). Mann–Whitney test. All data represented as mean  $\pm$  SEM. ns:  $p > 0.05$ , \*  $p < 0.05$ , \*\*  $p < 0.01$ , \*\*\*\*  $p < 0.0001$ . In a subset of experiments, tuft dendrites were traced to their soma of origin to measure the correlation of activity across dendritic branches of the same neuron (Extended Data Fig. 1–3).

overall dendritic pattern of activity. Taken together, we found a learning-related increase of auditory-evoked response in tuft dendrites of L2/3 pyramidal neurons, suggesting plasticity occurs within tuft dendrites following fear learning.

### CS+ and CS– evoke similar activity in basal dendrites

Does learning-related plasticity occur throughout an individual neuron, or is it compartmentalized to specific dendritic regions? To test this, we assessed whether fear learning also influences the processing of sensory information in the basal dendrites of L2/3 pyramidal neurons. Following the fear conditioning protocol, auditory-evoked  $\text{Ca}^{2+}$  activity was recorded in basal dendrites ( $>100 \mu\text{m}$  below pia; Fig. 2*a,b*). In contrast to tuft dendrites, CS+ and CS– evoked similar activity in basal dendrites, with no difference in the peak amplitudes (CS+:  $0.78 \pm 0.04$ ; CS–:  $0.90 \pm 0.05$ ,  $n=56/61$  dendrites, 8 mice,  $p=0.25$ ; Fig. 2*c,d*) and integral of the auditory-

evoked  $\text{Ca}^{2+}$  responses (CS+:  $1.51 \pm 0.07 \Delta\text{F}/\text{F}\cdot\text{s}$ ; CS–:  $1.60 \pm 0.05 \Delta\text{F}/\text{F}\cdot\text{s}$ ;  $n=56/61$  dendrites, 8 mice,  $p=0.39$ ; Fig. 2*d*). These findings suggest that the processing of sensory information in basal dendrites is not influenced by fear learning. To confirm that the auditory-evoked  $\text{Ca}^{2+}$  responses in basal dendrites was independent of stimuli exposure, we compared the  $\text{Ca}^{2+}$  response to both CS+ and CS– with a reference stimulus composed of a train of tones (5  $\times$  500 ms, 10 kHz) not previously presented to the mice (10 kHz:  $1.56 \pm 0.05 \Delta\text{F}/\text{F}\cdot\text{s}$ ;  $n=64$  dendrites; Extended Data Fig. 2–1). Here, there was no significant difference in the auditory-evoked  $\text{Ca}^{2+}$  responses of the reference stimulus compared with CS+ ( $p=0.47$ ) and CS– ( $p=0.34$ ; Fig. 2*e*). Furthermore, the average  $\text{Ca}^{2+}$  responses evoked by the reference stimulus were similar in both tuft and basal dendrites ( $p=0.34$ ; Extended Data Fig. 2–1), suggesting that neither the depth of recordings nor a spatially disparate influence of anesthesia contributed to the reported differences in the evoked  $\text{Ca}^{2+}$  activity in tuft and basal dendrites following fear

**Figure 2.** CS+ and CS- evoke similar responses in basal dendrites. **a**, Top, Schematic of the experimental design. learning. Taken together, these results suggest that, unlike in tuft dendrites, plasticity does not occur in the basal dendrites of L2/3 pyramidal neurons following fear learning.

### Action potential output is increased following fear learning

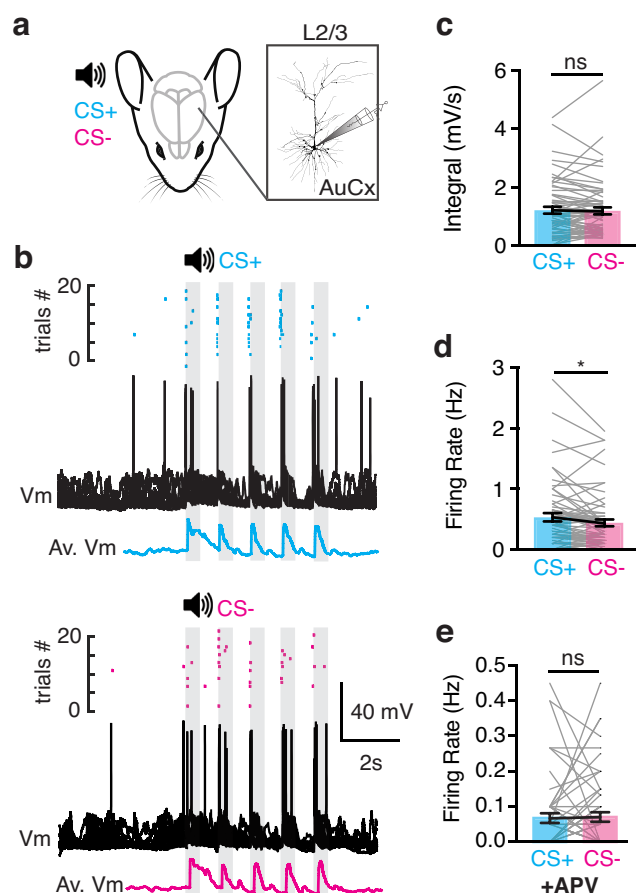

Learning-related plasticity in tuft dendrites may increase the efficacy of distal inputs on the somatic output (Palmer et al., 2014). Therefore, we next assessed whether somatic activity is influenced by fear learning. To measure the somatic voltage response to CS+ and CS- auditory stimuli, whole-cell patch clamp recordings were performed from L2/3 pyramidal neurons in the auditory cortex of urethane anaesthetized mice following fear conditioning (Fig. 3a,  $n = 13$  neurons, 10 mice; see Materials and Methods). Here, each tone within CS+ and CS- evoked a robust response consisting of a subthreshold voltage envelope and action potentials (Fig. 3b). Both CS+ and CS- evoked a similar subthreshold response (CS+,  $1.20 \pm 0.11$  mV/s; CS-,  $1.18 \pm 0.11$  mV/s;  $n = 13$  neurons, 10 mice;  $p = 0.35$ ; Fig. 3c). However, in contrast to the subthreshold response, the evoked firing rate was significantly greater during CS+ compared with CS- (CS+  $0.53 \pm 0.06$  Hz vs CS-  $0.44 \pm 0.05$  Hz;  $n = 13$  neurons, 10 mice;  $p = 0.01$ ; Fig. 3d). These results illustrate that fear learning enhances somatic action potential output in the absence of detectable changes in the subthreshold voltage. This discrepancy suggests that the greater evoked firing rate during CS+ is not simply driven by the

linear somatic summation of synaptic inputs, and may be because of dendritic electrogenesis which has previously been shown to directly generate action potentials without a measurable influence on subthreshold voltage (Larkum et al., 2009; Palmer et al., 2014). To test whether somatic output is influenced by modulating synaptic input in the upper cortical layers where distal dendrites reside, we locally applied the NMDA-receptor blocker APV onto the cortical surface while recording somatic voltage activity. Block of NMDA-dependent events in the upper cortical layers significantly dampened somatic activity and abolished the increased action potential rate following fear learning (CS+:  $0.06 \pm 0.01$  Hz vs CS-:  $0.07 \pm 0.01$  Hz;  $p = 0.73$ ; Fig. 3e). These results suggest that fear learning enhances the somatic output of L2/3 pyramidal neurons within the auditory cortex, which is dependent on synaptic activation of NMDA channels in the upper cortical layers.

### Control of the somatic output by tuft dendrites

Our experimental findings demonstrate that, following fear learning, auditory-evoked responses are enhanced in both the tuft dendrites and cell bodies of L2/3 pyramidal neurons. Does this increase in auditory-evoked signaling in tuft dendrites explain the changes in somatic firing rates following fear conditioning? To investigate this, we examined the influence of changes in synaptic input to tuft and basal dendrites on action potential generation using the NEURON simulation platform (see Materials and Methods; Fig. 4a; Extended Data Fig. 4-1). We modelled

the relationship between the number of synaptic inputs to the tuft and basal dendrites that are required to generate the somatic action potential output recorded in the experimental data (Fig. 4b). During the auditory stimulus period, we simulated an increasing number of tuft (or basal) inputs with a constant 200 basal (or tuft) inputs. Overall, less synaptic inputs were required in tuft dendrites (210–215 synapses) compared with basal dendrites (220–245 synapses) to drive somatic action potential output that corresponded to the experimentally measured mean firing rate during CS- and CS+, respectively (Fig. 4c). These findings suggest that, given the nonlinear electrotonic nature of the tuft dendrites, not only is it plausible for changes in the tuft

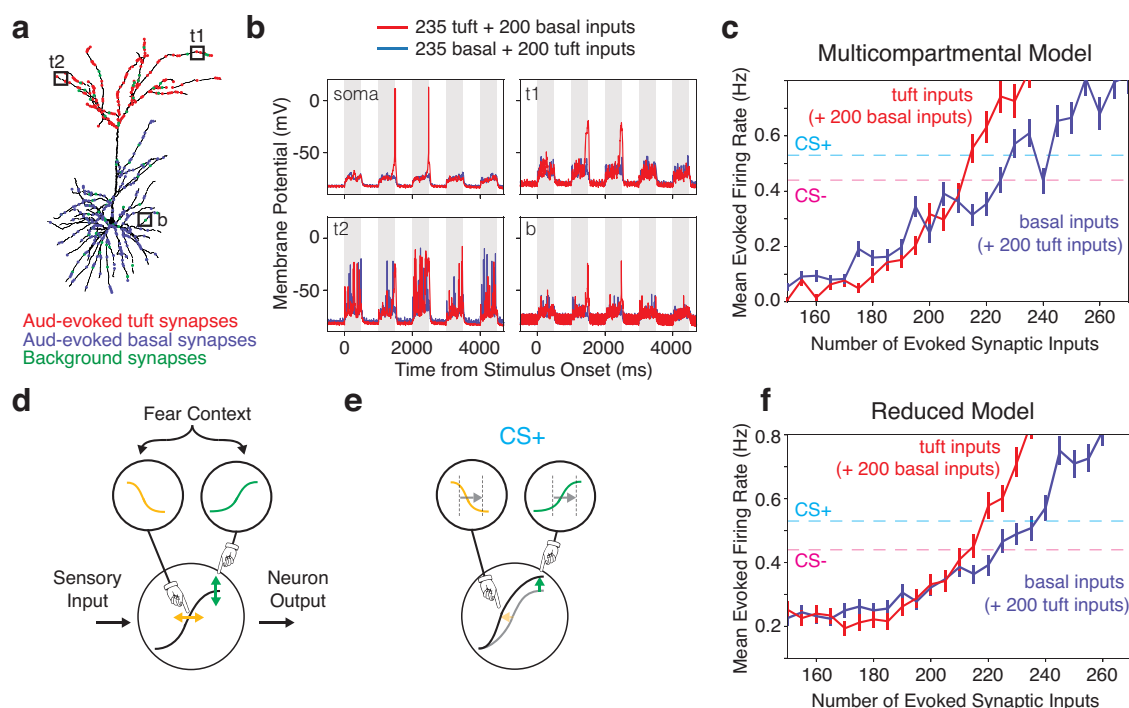

dendrites to account for our experimental results, tuft input can have a greater influence on somatic output compared with basal inputs, despite being further from the action potential initiation zone. To more intuitively understand how the nonlinearities in the pyramidal neurons can lead to changes in firing rates associated with fear conditioning we implemented a composite sigmoid model that explicitly represents the nonlinear interaction of the tuft and basal dendrites via two tuft sigmoids that control the maximum and threshold of the neurons input-output function (Fig. 4d). In this model, increasing excitatory input into the tuft dendrite decreases the threshold and increases the maximum value of the neurons input-output function in a nonlinear manner (Fig. 4e). Using this model, we simulated changes in tuft and basal inputs analogously to the simulations in the multicompartmental model. We found qualitatively similar results in this vastly simplified model (Fig. 4f), which in this case were easier to interpret. Increasing the basal inputs in both models resulted in a more linear response in output frequency compared with increasing tuft inputs. Furthermore, the results changing the basal versus tuft inputs diverged near the output firing rates associated with empirically measured CS- and CS+ conditions in our experiments. These results suggest that the L2/3 pyramidal neurons in our experiments could be taking advantage of the tuft nonlinearity to use a modest change in inputs to control the response to conditioned stimuli. Therefore, compartmentalized learning-related plasticity in tuft dendrites may provide a mechanism to increase the effect of distal feedback inputs on the somatic output, increasing the computational ability and flexibility of L2/3 pyramidal neurons.

## Discussion

The dendrites of pyramidal neurons dynamically encode sensory stimuli and perception (Xu et al., 2012; Palmer, 2014; Takahashi et al., 2016, 2020; Ranganathan et al., 2018) and are known to support different forms of plasticity (Holthoff et al., 2006; Makino and Malinow, 2011; Cichon and Gan, 2015; Brandalise et al., 2016; Sandler et al., 2016; Bittner et al., 2017; d'Aquin et al., 2022; O'Hare et al., 2022; Otor et al., 2022). Using two-photon  $\text{Ca}^{2+}$  imaging and patch clamp electrophysiology in L2/3 pyramidal neurons within the auditory cortex, we found that fear learning increases somatic output and enhances auditory-evoked  $\text{Ca}^{2+}$  responses in tuft, but not basal, dendrites. These results suggest fear learning enhances sensory processing in specific dendritic compartments, illustrating dendritic compartmentalization of learning-related plasticity.

The results in this study contribute to a growing body of evidence that shows the auditory cortex undergoes plasticity following auditory-fear learning (Romanski and LeDoux, 1992; Letzkus et al., 2011; Yang et al., 2016; Abs et al., 2018), where auditory-evoked activity in pyramidal neurons change both morphologically (Yang et al., 2016; Lai et al., 2018) and functionally (Weinberger and Diamond, 1987; Quirk et al., 1995; Letzkus et al., 2011; Gillet et al., 2018; Dalmay et al., 2019). Our findings also confirm the important role of cortical layer 1, where tuft dendrites reside, in driving

**Figure 4.** Control of the somatic output by tuft dendrites. **a**, Schematic of the simulation design. A reconstructed L2/3 pyramidal neuron was used for a multicompartmental model. Background synapses (green dots) were distributed uniformly across the neuron, while auditory-evoked synapses were distributed uniformly across the basal (blue dots) or tuft dendrites (red dots; see also Extended Data Fig. 4-1). **b**, To simulate auditory-evoked responses in this L2/3 neuron, we put either 235 tuft and 200 basal (red traces), or 235 basal and 200 tuft (blue traces) auditory-evoked synapses during a  $5 \times 500$  ms stimulation window. Example membrane potentials during these two simulation conditions are shown for two tuft locations (labels t1 and t2 in panel a), the soma, and for one basal location (label b in panel a). **c**, To see how changes in tuft and basal inputs change the output of the neuron, we simulated an increasing number of auditory-evoked tuft inputs with a constant 200 basal auditory-evoked inputs (red) and an increasing number of auditory-evoked basal inputs with a constant 200 tuft auditory-evoked inputs (blue). Error bars are SEM. Dotted lines denote the experimentally determined mean firing rates for the CS+ (cyan) and CS- (magenta) conditions. **d**, Schematic of the reduced model using two sigmoids to represent tuft inputs controlling the maximum (green) and threshold (orange) of the neuron input output function. **e**, Compared with CS-, the neuron input output function has a decreased threshold (orange) and increased maximum (green) in response CS+ (illustrated by arrows). **f**, The reduced model is able to recapitulate the simulation results from the multicompartmental model in c).

these changes (Abs et al., 2018; Doron et al., 2020). Here, we demonstrate that auditory-evoked  $\text{Ca}^{2+}$  responses are specifically increased in apical tuft dendrites following fear learning. Such changes were not observed in basal dendrites, suggesting learning-related neuronal compartmentalization of dendritic plasticity. This dendrite-specific plasticity is not unique to cortical pyramidal neurons as recent studies have also reported compartmentalized plasticity in the lateral amygdala (d'Aquin et al., 2022) and hippocampus (O'Hare et al., 2022). Taken together, these results illustrate that neurons are multicompartmental (Häusser and Mel, 2003) which, by providing neurons with multiple independent integrative units that process information in parallel, increases the computational power of a single neuron (Poirazi et al., 2003; Jädi et al., 2014; Ujfalussy et al., 2018).

In addition to increasing the computational power of pyramidal neurons, compartmentalized experience-dependent plasticity may also provide a cellular mechanism to gate information received by a neuron, specifically enhancing the impact of certain input pathways. Since the tuft dendrites of pyramidal neurons are the target of long-

range feedback projections from the fear pathway (Yang et al., 2016), the enhanced activity in tuft dendrites may act to ensure this synaptic pathway has a greater influence at the cell body. Indeed, we found experimental evidence that tuft dendrites strongly influence somatic output, increasing the effect of distal synaptic inputs on the cellular output. This was supported by two computational models of different complexity, which both showed that tuft inputs can have a greater influence on somatic output compared with basal inputs, despite being further from the action potential initiation zone. This may be a key mechanism to dynamically enhance top-down control over sensory encoding which is required during learning (Makino and Komiyama, 2015). The strong influence of tuft dendrites on somatic firing in our study is in agreement with other studies (Palmer et al., 2014; Goetz et al., 2021) showing that small changes in the synaptic inputs onto the distal dendrites of L2/3 pyramidal neuron can dynamically drive somatic activity (Goetz et al., 2021). This was further illustrated experimentally by pharmacologically modulating the synaptic input within layer 1

by blocking NMDA channels which decreased somatic action potentials. Together, our findings suggest that synaptic input onto basal and tuft dendrites may have different roles in contributing to the overall excitability of individual neurons. Since learning requires flexibility in sensory representation, plasticity within different dendritic compartments may dynamically shift the balance between feedback (tuft) and feedforward (basal) information onto a single neuron, resulting in flexible sensory encoding throughout learning (Jordan and Keller, 2020).

In this study, fear learning specifically caused an increase in the  $\text{Ca}^{2+}$  transient evoked in response to CS+ in tuft, and not basal, dendrites. The cause of this compartmentalized  $\text{Ca}^{2+}$  increase is unknown and could be because of both presynaptic and postsynaptic processes. For example, the increase in the tuft response following fear learning may be due to postsynaptic modification of synaptic weight, which can change the synaptic response to incoming input through long-term potentiation (Fusi and Abbott, 2007; Nabavi et al., 2014). Likewise, presynaptic modification of synaptic input from brain regions known to be essential for fear conditioning (LeDoux, 2000; Maren and Quirk, 2004) may also drive the increase in the tuft response to conditioned stimuli by altering their firing patterns and synaptic targets within the auditory cortex (Yang et al., 2016). Previous studies report that global  $\text{Ca}^{2+}$  signaling may result from backpropagating action potentials (Wilson et al., 2016; Iacuruso et al., 2017; Beaulieu-Laroche et al., 2018; Francioni et al., 2019; Kerlin et al., 2019). Although backpropagating action potentials may contribute to the dendritic  $\text{Ca}^{2+}$  signal recorded in our study, we suggest that they do not drive the compartmentalized increase in  $\text{Ca}^{2+}$  signaling within tuft dendrites as we would expect to see a similar change in the  $\text{Ca}^{2+}$  response in basal dendrites, which was not the case. Our findings further suggest that intracellular calcium stores also did not primarily drive the changes in dendritic  $\text{Ca}^{2+}$  responses, as fear learning did not alter the spatial pattern of dendritic activity which has recently been shown to be influenced by intracellular calcium release (O'Hare et al., 2022). Additional in-depth experiments are required to determine the presynaptic and/or postsynaptic modifications which drive the reported changes in dendritic signaling following fear learning, which is an exciting new avenue for future research.

It is important to note that the experiments reported in this study were performed under urethane anesthesia as, compared with other common anesthetic, urethane has been shown to have a comparatively smaller influence on dendritic processing (Potez and Larkum, 2008). Although anesthesia reduces overall feedback activity in the cortex (Boly et al., 2011; Murphy et al., 2019), our findings illustrate that plasticity can still occur in the distal dendrites that are targeted by feedback input. Our results also suggest that the enhanced neural activity following fear learning is probably not because of arousal pathways or movement which are abolished during anesthesia (Salay et al., 2018; Bigelow et al., 2019; Stringer et al., 2019). Therefore, the differences in sensory processing following fear learning reported in this study illustrates the robust

nature of the enhanced signaling as it was observed even when feedback pathways were dampened.

In summary, we identified compartmentalized learning-related plasticity in the processing of auditory stimuli in the tuft dendrites and somatic output of L2/3 pyramidal neurons. This is in direct contrast to the long held (and debated) hypothesis that, despite extensive dendritic arbors, neurons may function as a simple one-compartment model (Poirazi et al., 2003). The ability to adapt behavioral responses to the external environment relies on the flexibility of sensory representation that can be constantly updated through learning (Kato et al., 2015). Perhaps this is achieved through the increased cortical computation afforded by multiple independent integrative units, which may provide a cellular mechanism for the control of neural output during learning.
